Abstract

Soil quality strongly influences the growth of vegetation and other environmental factors. While generating economic value, mining activities also damage soil and vegetation. Ecological restoration of areas subjected to mining activities has become a major cost borne by government agencies and mining enterprises. Restoration depends on comprehensive assessment of soil and environmental quality. This study addressed impacts of subsidence occurring around the Bulianta Coal Mine of the Shenfu coalfield in China. Using non-subsiding areas as a control, the research compared soil quality parameters defined by the Integrated Fertility Index (IFI) and Potential Ecological Risk Index (RI) frequently used in environmental monitoring and remediation. The results showed that subsided areas exhibited greater soil bulk density (SBD) and pH values relative to soils from areas not experiencing subsidence. Soils from subsided areas contained lower available nitrogen (AN), available potassium (AK), organic matter (SOM) relative to soils from non-subsidence areas. Different soil layers also exhibited considerable variation in available phosphorus (AP), AK, and SOM that attained significance at the $P < 0.05$ level. Soils from subsided areas showed lower concentrations of Cd, Cu, Pb, and Zn than that measured from non-subsidence areas. The heavy metal content of non-subsided soils varied considerably with the depth of soil layer analyzed. Lead was the most abundant species of heavy metal detected in the soil of the mining area, and Cd showed the greatest potential risk of soil pollution in the mining area. The soil fertility index in the study area depended on subsidence, which showed some degree of spatial continuity. The subsided area showed poor soil quality and the entire area categorized as a slight potential ecological

risk. This research supports management and ecological restoration of the mining area and may serve as a reference for similarly impacted areas around the world.

Keywords: soil fertility evaluation, environmental quality evaluation, heavy metals, coal mining subsidence, semi-arid areas

Introduction

Coal is one of the top three energy sources in the world and accounts for a third of the world's energy consumption [1]. Coal resources account for 70% of China's energy resources and will thus remain an important component of China's energy portfolio for the foreseeable future [2]. At present, subsurface mining is the predominant mining methodology used to access coal resources. As one of the seven largest coal fields in the world, the Shenfu-Dongsheng coalfield exerts major impacts on its surrounding environment due to the scale of resource extraction. Impacts include ground subsidence, soil erosion, loss of soil productivity, and other forms of ecological deterioration [3-4]. Impacts associated with mining-induced land subsidence have drawn international scientific interest. Specifically, researchers have sought to understand how to restore soil function in the mining area [5].

Soil fertility depends on nutrient availability and specific environmental requirements of different types of vegetation. Soil fertility can be constrained by soil physical properties which influence the growth of vegetation [6]. Mark et al. [7] studied the effects of ground subsidence on soil properties, hydrology, and topography. Zhao et al. [8] found that coal mining subsidence caused changes in soil mechanical properties and a decrease of fine particulate matter in surface soil. Due to the arid climate and windy conditions, these impacts enhanced wind erosion of soil in the study area. Wang et al. [9] found that soil fertility in the Shendong mining area was poor due to low levels of organic matter, nitrogen, and phosphorous. Wang et al. [10] found that land subsidence around subsurface mines and other human disturbances exerted significant environmental impacts in areas with semi-arid climates. Soil quality parameters are included in soil biological and chemical indices as well as in other comprehensive estimates of environment quality [11-12].

Considerable research has focused on soil quality due to its role in environmental risk evaluation [13]. Soils can contain around 90% of environmental pollutants including heavy metal species that represent the greatest health hazards. Coal mining activities effectively expose and mobilize heavy metals through extraction, processing, transportation, and utilization [14]. Research on heavy metal pollution in soils from mining activities mainly focuses on their spatial distribution within established frameworks of hazard assessment and remediation [15-18]. Liu et al. [19] found that coal mines influenced nutrients and heavy metal

content in the 0-10 cm soil layer around the mining area. The SOM and AN contents correlated negatively with Pb, Cr, Cu, and As concentrations in the soil. Du et al. [20] found significant accumulations of Hg, Cr, Zn, As, and Cu in soil from the northern Shenmu mining area. In their study of soils surrounding coal gangue of the Shenfu mining area, Liu et al. [21] detected Pb, Zn, Cu, and Cd at levels that greatly exceeded background values. Concentrations of Pb and Cd categorized as posing medium environmental risk. In recent years, methods for managing and remediating coal mining sites have transitioned from resting primarily on qualitative descriptions to resting on more quantitative evaluations. While researchers still use a range of methods, quantitative evaluation of soil quality enlists geostatistics and other numerical methods that can detect critical patterns in soil parameters [22-24]. Many studies on heavy metal contamination in soils around coal mining areas and associated risk assessment tend to use a single factor pollution index, the Nemerow index, the geoaccumulation index, a potential ecological hazard index method, or other indices [25-26], but few approaches use a suite of heavy metal measurements.

Land use planning, soil resource management, and remediation efforts all depend on accurate soil quality estimates. Restoration efforts in areas where mining has significantly damaged the environment also use soil quality estimates to manage pollution and other risks [27]. Studies on soil quality have demonstrated the interrelation of these two parameters and the need for more in depth analysis of environmental quality. Few studies have used multiple soil parameters to comprehensively evaluate pollution in areas subject to mining-induced land subsidence.

Developed and built by the Shendong Coal Group, the Bulianta Coal Mine is the largest underground coal mine in the world. The Shendong mining area experiences extensive land subsidence due to coal mining [28]. Using the Bulianta Coal Mine as a study area, this research applied fuzzy mathematics to the integrated fertility index (IFI) evaluation model and the potential ecological risk index (RI) to comprehensively evaluate soil quality and heavy metal pollution in both subsided and non-subsidence areas near and overlying the coal mine. The objectives of the study were (1) to determine sensitivity of the soil fertility index in subsided areas and (2) evaluate mining impacts through a comprehensive evaluation of soil quality in the subsided area. The results of the study provide a theoretical basis for mitigation and restoration efforts that manage impacts from resource development.

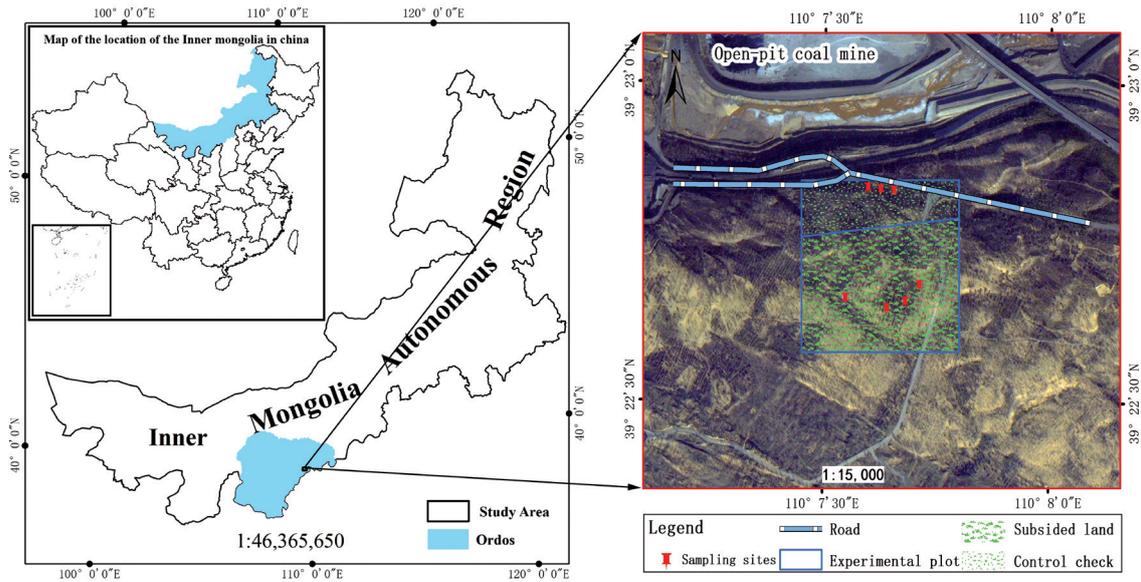

Fig. 1. Location of the study area.

Materials and Methods

Study Area

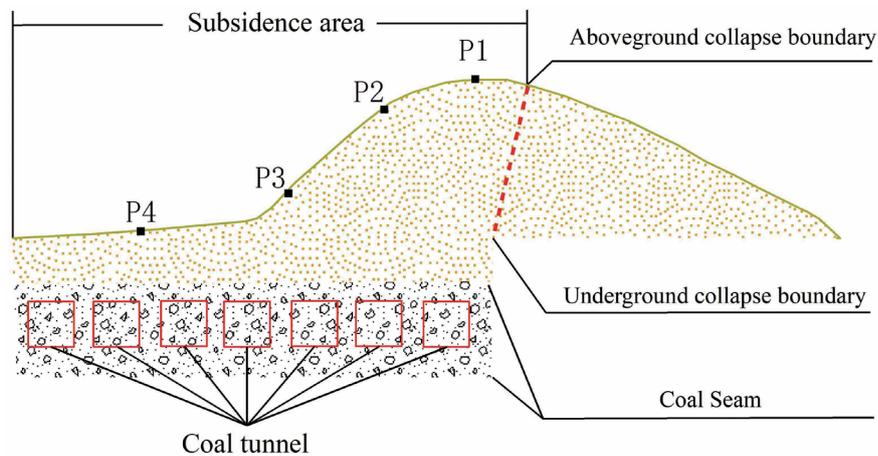

The Bulianta Coal Mine of the Shenfu Coalfield is located along the border of the Inner Mongolia Autonomous Region and Shaanxi Province (Fig. 1). It lies in a northeastern region of the large, coal-rich Ordos basin along the southeastern edge of Mu Us Sandy Lands of the Ordos Plateau. In terms of administrative boundaries, it belongs to Wulanmulun Town of Ejin Horo Banner, Ordos. Its spans $109^{\circ}45'$ to $110^{\circ}40'E$ and $38^{\circ}50'$ to $39^{\circ}50'N$. With recoverable reserves of 1.24 billion tons, the Bulianta Coal Mine began operation in October 1997 and covers a 106.6 km^2 area. Lying between 1100 and 1300 m elevation, the area experiences a typical arid to semi-

arid continental climate. During the study, the annual rainfall ranged from 194.7 to 531.6 mm, and the annual evaporation ranged from 2297.4 to 2838.7 mm. The main types of soil in this area are aeolian soil and sandy loam, most of which takes the form of fixed and semi-fixed sand. The study area hosts sandy vegetation, low wetland vegetation, and artificial vegetation of the steppe zone. The natural vegetation consists primarily of herbaceous communities.

Sample Location and Sampling

Sample Selection

Two sites south of the Bulianta Coal Mine were selected and sampled in July 2019 due to their consistently sandy soil parent material and consistent

P1—Roof of slope; P2—Mid of slope; P3—Base of slope; P4—Dune lowland

Fig. 2. Diagram of sampling sites.

underlying dune surface conditions. An area of dunes to the north showed no evidence of subsidence due to coal mining subsidence and was treated as a control area (denoted as CK or referred to as the non-subsidence area). Dunes to the south showed clear evidence of subsidence (Fig. 2) from collapse in 2004 (denoted as TX collapse and referred to as the subsided area).

Soil Sampling

Soil profiles extending 1 m down from a 1×1m² area were trenched along the roof, middle, and base of the slope of a dune in the non-subsided area. Similar 1 m deep and 1 x 1 m² soil profiles were trenched along the roof, middle, and base of slopes for dunes above and below a fissure and lowland dune in a subsided zone (Fig. 3). A multi-point sampling method was used along each of the three soil profiles. Three duplicate samples were collected from the same soil profile at 0-5 cm, 5-20 cm, 20-40 cm, 40-60 cm, 60-80 cm, and 80-100 cm depth.

Experimental Methods

Samples were transported to and analyzed at the laboratory. Soil organic matter (SOM) was determined by a potassium dichromate external heating method. Soil available nitrogen (AN) was determined by the Kjeldahl nitrogen method. Available phosphorus (AP) was determined using a 0.5 mol·L⁻¹ NaHCO₃ extraction method and available potassium (AK) was determined by the flame photometric method. Soil heavy metal concentrations (Cu, Cd, Pb, and Zn) were measured by Laser-induced Breakdown Spectroscopy (LIBS). The pH value of soil was determined by the potential

method (PXJ-IC pH meter). Soil bulk density (SBD) was determined by the cutting ring method.

Statistical Analysis

This study conducted traditional statistical analysis and principal component analysis using SPSS 25.0 and Excel 2016. Comparisons and graphs were constructed using OriginPro 9.0. Differences in soil fertility estimates for different soil layers were analyzed using one-way ANOVA and multiple comparisons (LSD). Soil fertility and heavy metal concentrations were compared and analyzed using traditional statistical methods. These included mean, minimum, maximum, skewness, kurtosis, standard deviation, and coefficient of variation. Pearson correlation coefficients were used to interpret relationships between different fertility indexes and different heavy metal pollution indexes.

Comprehensive Evaluation of Soil Fertility

Types of the Membership Function and Thresholds of Soil Fertility Index

The measured soil parameters were normalized to resolve differences in dimensions for each parameter to allow for comparisons. The fuzziness and continuity of indexes warranted standardization with a membership function. Fuzzy mathematical approaches helped establish the corresponding membership function for the fertility index [29-30]. The AN, AP, AK, and SOM parameters were assigned an S-type membership function wherein membership was calculated according to formula (1):

Fig. 3. An aboveground fissure indicating subsidence (left) and a soil profile (right).

Table 1. Types of the membership function and thresholds for soil fertility index.

| Types of the membership function | Soil fertility index | Thresholds | | | |
|----------------------------------|--------------------------|------------|-------|-------|-------|
| | | x_1 | x_2 | x_3 | x_4 |
| Parabolic | SBD (g/cm ³) | 1.25 | 1.35 | 1.45 | 1.55 |
| | pH | 4 | 6.5 | 8 | 9 |
| S-type | AN (mg/kg) | 25 | | | 40 |
| | AP (mg/kg) | 1 | | | 3 |
| | AK (mg/kg) | 20 | | | 40 |
| | SOM (g/kg) | 0.75 | | | 10 |

$$f(x) = \begin{cases} 0.1, & x \leq x_1 \\ 0.9 \times \frac{x-x_1}{x_4-x_1} + 0.1, & x_1 < x < x_4 \\ 1, & x \geq x_4 \end{cases} \quad (1)$$

...where $f(x)$ represents the plant growth membership function of the parameter and x represents the measured value of the fertility index.

SBD and pH were assigned a parabolic membership function calculated as follows (2):

$$f(x) = \begin{cases} 0.1, & x \leq x_1 \text{ or } x \geq x_4 \\ 0.9 \times \frac{x-x_1}{x_2-x_1} + 0.1, & x_1 < x < x_2 \\ 1, & x_2 \leq x \leq x_3 \\ 1 - 0.9 \times \frac{x-x_3}{x_4-x_3}, & x_3 < x < x_4 \end{cases} \quad (2)$$

...where $f(x)$ represents the plant growth membership function of the parameter and x represents the measured value of the fertility index.

The threshold value for membership functions was derived from a combined interpretation of literature sources [31], the soil classification standards given in the Second National Soil Survey Technical Regulations of China [32], and situational factors for the research area. Table 1 lists membership function threshold value ranges.

Determination of Soil Fertility Index Weightings

Principal component analysis (PCA) helps reduce the dimensionality of datasets by calculating a common factor variance and a set of weightings for soil parameters. Bartlett's test of sphericity applied to soil data gave a KMO value of 0.641 and sig = 0.00 < 0.01 verifying that principal component analysis offers analytical benefits. The first two principal components had eigenvalues >1 and accounted for 60.143% of the variation. This indicates that these two component identify meaningful associations among measured parameters. Table 2 lists weightings of soil parameters for the two highest ranked components.

Comprehensive Evaluation of Soil Fertility

The Integrated Fertility Index (IFI) was calculated using the weighted sum index model provided by fuzzy mathematics [33]. Formula (3) was used to calculate IFI:

$$IFI = \sum_n^i W_i \cdot N_i \quad (3)$$

...where W_i represents the weight of the index i , N_i represents the membership value of the index i , and n represents the number of indices evaluated.

Table 2. PCA weightings of soil fertility index.

| Soil fertility index | Principal component | | Communality | Weight |
|----------------------|---------------------|--------|-------------|--------|
| | 1 | 2 | | |
| SBD | -0.615 | 0.14 | 0.398 | 0.110 |
| pH | -0.302 | 0.821 | 0.765 | 0.212 |
| AN | 0.402 | 0.66 | 0.597 | 0.166 |
| AP | 0.631 | -0.035 | 0.399 | 0.111 |
| AK | 0.835 | 0.191 | 0.734 | 0.203 |
| SOM | 0.842 | -0.082 | 0.715 | 0.198 |
| Eigenvalue | 2.435 | 1.173 | | |
| Cumulative (%) | 40.587 | 60.143 | | |

Table 3. Pollutions levels designated by the Nemerow composite index.

| Nemerow comprehensive pollution index (P_N) | Grade | Pollution level |
|---|-------|--------------------------|
| $3 < P_N$ | 5 | High levels of pollution |
| $2 < P_N \leq 3$ | 4 | Moderate pollution |
| $1 < P_N \leq 2$ | 3 | Light pollution |
| $0.7 < P_N \leq 1$ | 2 | Clean (warning) |
| $P_N \leq 0.7$ | 1 | Unpolluted (safe) |

Evaluation of Soil Heavy Metal Pollution

Evaluation of Pollution Status of Soil Heavy Metals

Single factor index evaluation represents one of the commonly used methods for evaluating degrees of pollution in soil [34]. Its formula is:

$$P_i = C_i/S_i \tag{4}$$

...where P_i is the pollution index of soil pollutant i , C_i is the measured mass fraction of pollutant i in mg/kg, and S_i is the evaluation standard value of pollutant i (Chinese Soil Environmental Quality Standard GB 15618-1995 [35], see Table 7) in mg/kg.

The Nemerow comprehensive pollution index reflects the average pollution level for each pollutant in the soil and also highlights the harm caused by the most serious pollutant to the environment [36]. Its formula is:

$$P_N = \sqrt{\frac{P_{imax}^2 + P_{iave}^2}{2}} \tag{5}$$

...where P_N is the comprehensive pollution index, P_{imax} is the maximum value of the pollution index for each pollutant, and P_{iave} is the arithmetic mean value of the pollution index for each pollutant. According to the Nemerow comprehensive pollution index, soil heavy metal pollution divides into five levels listed in Table 3.

Potential Risk Associated with Soil Heavy Metals

The Potential Ecological Risk Index (RI) was calculated to evaluate the potential risk of heavy metals in study area soils. The RI calculation runs as follows:

$$C_r^i = \frac{C_i}{C_n^i} \tag{6}$$

$$C_p = \sum C_r^i \tag{7}$$

$$E_r^i = T_r^i \times C_r^i \tag{8}$$

$$RI = \sum E_r^i = \sum T_r^i \times C_r^i \tag{9}$$

...where, C_r^i is the pollution coefficient for a given heavy metal, C_i is the actual concentration of the heavy metal in soil, C_n^i is the pollutant concentration in the original parent material or biological sediments (using background values measured from Inner Mongolian soils [37] as listed in Table 7), C_p is the comprehensive pollution degree, E_r^i is the potential ecological risk coefficient of a given pollutant, and T_r^i is the toxicity response coefficient of a given pollutant (the toxicity response coefficients of elements Cd, Pb, Cu, and Zn are 30, 5, 5, and 1 respectively [38]). The RI represents a multi-factor potential ecological risk index. Table 4 lists risk levels associated with RI values.

Results

Soil Fertility Index in Coal Mining Subsidence Area

Table 5 lists statistics for parameters measured from surface (0-5 cm) and deeper (40-100 cm) soils in both subsided and non-subsidence areas. Mean SBD values exceed 1.55g /cm³ and soils showed very high bulk densities. The mean pH value exceeded 7.5 which indicates alkaline soils. The maximum pH value of 9.34 came from deep samples designating those soils as strongly alkaline. In terms of SOM, the mean of surface soil ranged from 20-30 g/kg which categorizes as the

Table 4. Risk levels for different comprehensive pollution and potential risk estimate ranges.

| Comprehensive pollution degree (C_p) | Pollution level | Potential ecological risk coefficient (E_r^i) | Risk level | Potential ecological risk index (RI) | Risk level |
|--|--------------------|---|---------------------------|--------------------------------------|--------------------------|
| $(C_p) < 8$ | Light pollution | $(E_r^i) < 40$ | Minor ecological hazard | RI < 150 | Minor ecological hazard |
| $8 \leq (C_p) < 16$ | Moderate pollution | $40 \leq (E_r^i) < 80$ | Medium ecological hazard | $150 \leq RI < 300$ | Medium ecological hazard |
| $16 \leq (C_p) < 32$ | Heavy pollution | $80 \leq (E_r^i) < 160$ | Heavy ecological hazard | $300 \leq RI < 600$ | Heavy ecological hazard |
| $(C_p) \geq 32$ | Strong pollution | $160 \leq (E_r^i) < 320$ | Strong ecological hazard | RI ≥ 600 | Strong ecological hazard |
| | | $(E_r^i) < 320$ | Extreme ecological hazard | | |

Surface soil occurred at 0-5 cm depth. Deep soil occurred at 40-100 cm depth. Statistics include standard deviation (SD), coefficient of variation in % (CV), skewness (Skew), and kurtosis (Kurto.)

“medium” level in the soil nutrient classification system. The mean SOM measured from deeper soils was less than 6 g/kg. The 0.99 g/kg value categorized as an “urgent shortage” level in the soil nutrient classification system. In terms of AN and AP, both surface and deeper soils gave mean values lower than the “emergency” level within the soil nutrient classification system, (30 mg/kg and 3 mg/kg, respectively). In terms of AK, the surface soil gave mean values ranging from 30-50 g/kg, which qualify as the “shortage” level in the soil nutrient classification system. Deeper soils gave mean values less than 30 g/kg which fall in the “urgent shortage” level. Surface soils showed greater spatial variation in SBD, AP, AK, and SOM than deeper

layers. Surface soils showed less variation in pH and AN than deeper layers. Spatial variation in surface soil parameters ranked as SOM>AK>AP>AN>SBD > pH. Spatial variation in deep layer soil parameters ranked as SOM>AP>AK>AN>SBD = pH.

Single-factor variance and multiple comparison analysis (Table 6) indicate that SBD, pH, AN, AP, AK, and SOM vary with different soil depths. With the increase of soil depth, SBD and pH initially increased and then decreased in both subsided and non-subsidence areas. AP content initially decreased and then increased. AK and SOM content all showed a downward trend. AN content initially decreased and then increased in the subsided area. In the non-subsidence area, AN content

Different capital letters indicate significant differences between different layers of TX and CK (P<0.05). Different lowercase letters indicate significant differences between TX and CK areas in the same soil layer (P<0.05).

initially increased and then decreased. Subsidence thus strongly influences AN in the vertical direction.

For subsided areas, the greatest differences in AN values appeared between the 5-20 cm and 60-100 cm soil layers ($P < 0.05$). AN did not show significant differences with depth between subsided and non-subsidence areas ($P > 0.05$). For the subsided area, AP differed strongly between the 5-20 cm, 0-5 cm, and 60-100 cm soil layers ($P < 0.05$). For non-subsidence areas, AP did not differ significantly between the 0-5 cm and 20-80 cm soil layers ($P < 0.05$). For the subsided area, AK content in subsided areas differed significantly between soil depths of 0-5 cm and 40-60 cm ($P < 0.05$). AK content in non-subsidence areas differed significantly between 0-5 cm and other soil depths ($P < 0.05$). SOM content in both the subsided and non-subsidence areas showed significant differences between the surface layer (0-5 cm) and all other soil layers ($P < 0.05$). In summary, excepting AN, the AP, AK and SOM measured from soils differed significantly between different soil layers ($P < 0.05$). AN only differed between different soil layers in the subsided area ($P < 0.05$).

On the whole, SBD measured for different depths of layers in the subsided area exceeded those measured from different layers of the non-subsidence area. Differences reached significant levels for depths of 40-60 cm ($P < 0.05$). Differences among different soil layers did not differ significantly between the subsided and non-subsidence areas ($P > 0.05$). Above the 60 cm soil layer, pH values for all depths of the subsided area exceeded those of the non-subsidence area. Subsided and non-subsidence areas however did not show significant differences for the same soil depths ($P > 0.05$). For the non-subsidence area, pH values for the 0-5 cm and 5-20 cm depths differed significantly from those of other soil layers ($P < 0.05$). Soils from the subsided

area did not show significant differences in pH values for different layers ($P > 0.05$). Subsidence appears to influence horizontal variation in SBD and pH. Relative to non-subsidence areas, subsided areas gave lower values of chemical parameters (AN, AK, and SOM) for each soil depth analyzed. Samples above the 20 cm layer for the subsided area gave higher AP content than those from the same layer of the non-subsidence area. Below the 20 cm layer, the subsided area gave higher AP values than those from the same layer of the non-subsidence area. The subsided and non-subsidence areas showed no significant difference between AN, AP, and SOM measured from corresponding soil layers ($P > 0.05$). However, AK did show significant differences for the 0-5 cm layer ($P < 0.05$). This indicates that subsidence can generate horizontal variation in AK and AP.

Analysis of Soil heavy Metal Pollution Index in Coal Mining Subsidence Area

The heavy metal concentrations measured from surface (0-5 cm) and deep (40-100 cm) soil layers of both subsided and non-subsidence areas were interpreted with reference to background values measured for Inner Mongolia and the Chinese Soil Environmental Quality Standards (Table 7). Generally, concentrations of Cd, Cu, Pb, and Zn were 2-3 times higher than background values from Inner Mongolian soils for both surface and deep soil layers. This indicates heavy metal pollution of study area soils. The Pb and Zn content in the surface soil were respectively 5% and 1% higher than the national environmental standard. The Cd and Cu contents of deep soil were respectively 10% and 9% higher than the national environmental standard. While concentrations of the four heavy metals fell below

Table 7. Descriptive statistics for heavy metal concentrations in soils (mg/kg).

| Statistical parameters \ Heavy metals | Cd | | Cu | | Pb | | Zn | |
|---------------------------------------|--------------|-----------|--------------|-----------|--------------|-----------|--------------|-----------|
| | Surface soil | Deep soil |
| Min | 0.12 | 0.13 | 18.94 | 19.20 | 30.10 | 32.49 | 80.87 | 85.41 |
| Max | 0.19 | 0.19 | 29.17 | 29.78 | 45.83 | 46.13 | 132.74 | 136.6 |
| Mean | 0.14 | 0.15 | 23.47 | 24.61 | 36.80 | 38.64 | 100.5 | 108.80 |
| SD | 0.02 | 0.02 | 2.98 | 3.86 | 5.99 | 5.07 | 18.86 | 20.48 |
| Skew. | 1.13 | 0.19 | 0.39 | 0.20 | 0.44 | 0.14 | 0.77 | 0.18 |
| Kurto. | 0.85 | -1.76 | 0.12 | -1.65 | -1.61 | -1.72 | -0.39 | -1.95 |
| CV | 0.16 | 0.16 | 0.13 | 0.16 | 0.16 | 0.13 | 0.19 | 0.19 |
| Background value | 0.05 | | 13.92 | | 16.85 | | 56.61 | |
| Secondary Standard | 1.00 | | 100.00 | | 350.00 | | 300.00 | |
| Primary Standard | 0.20 | | 35.00 | | 35.00 | | 100.00 | |

The surface soil ranged from 0-5 cm depth. The deep soil ranged from 40-100 cm depth. The statistical parameters reported include standard deviation (SD), coefficient of variation in % (CV), skewness (Skew.), and kurtosis (Kurt.).

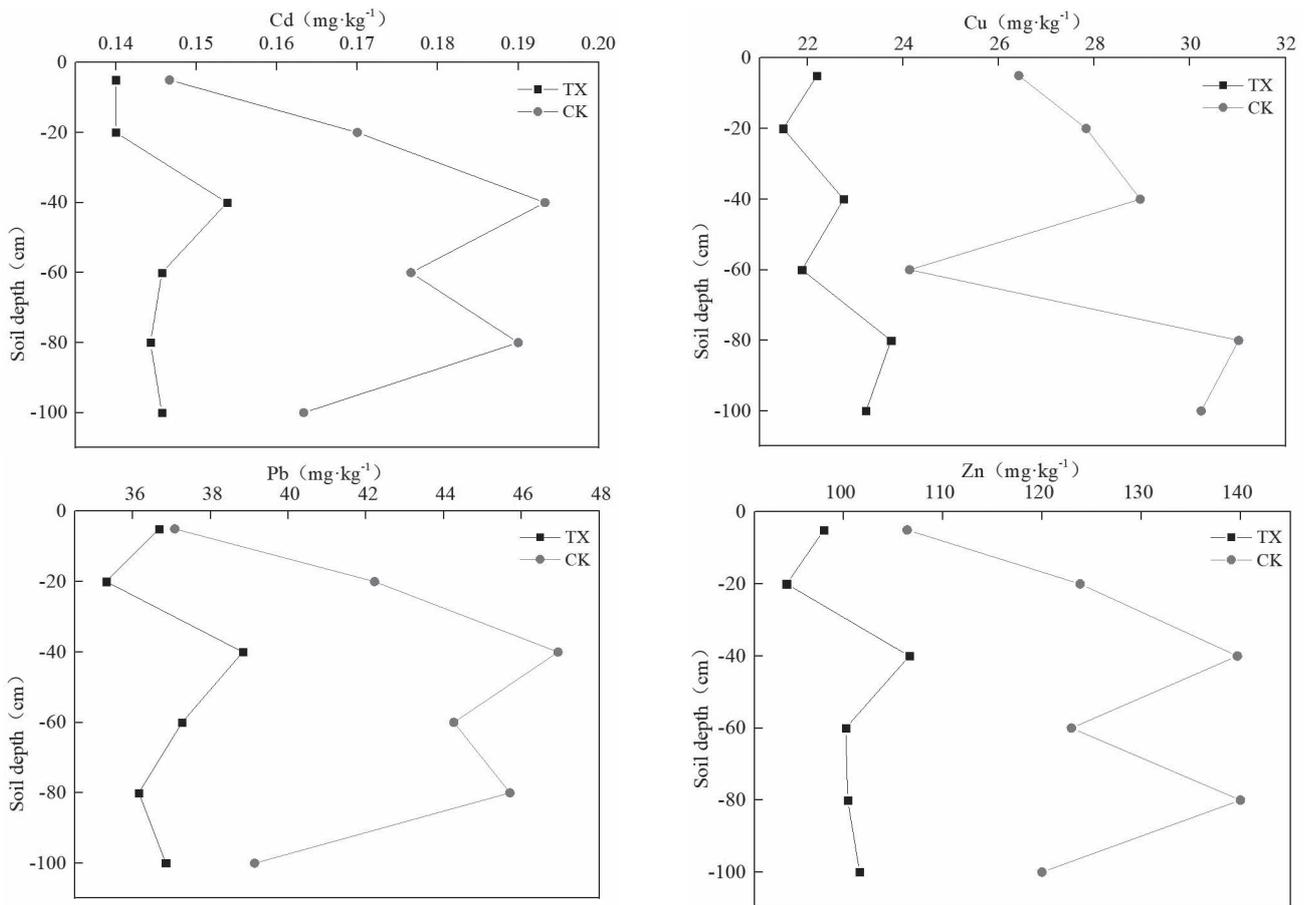

Fig. 4. Vertical distribution of heavy metal species in soils.

values listed in the national secondary environmental standards, values showed gradual increase with depth. The Cd, Cu, Pb, and Zn concentration also showed moderate spatial variation. For surface layers, the degree of spatial variation for each element ranked as Zn>Cd = Pb>Cu in surface soils. In deep soils, degree of spatial variation ranked as Zn>Cd = Cu>Pb. Variation in heavy metal content with depth (Fig. 4) shows that non-subsidence areas contained higher concentrations of heavy metals relative to those measured from subsided area soils. In the 0-40 cm soil layer, Cd, Cu, Pb, and Zn increased with depth in the non-subsidence area. The Cd, Cu, Pb, and Zn concentrations initially decreased and then increased with depth in the subsided area. For the 40-80 cm soil layer, Cd, Cu, Pb, and Zn concentrations initially decreased and then increased with soil depth. Heavy metals varied greatly with the depth in soils from the non-subsidence area.

Correlation of Soil Parameters and Heavy Metal Concentrations

Table 8 lists correlations between SBD, pH, AN, AP, AK, and SOM soil parameters and heavy metal concentrations (Cd, Cu, Pb, and Zn). This table shows that pH, AN, AP, AK, and SOM do not significantly correlate with the heavy metals measured from

soils. The Cd, Pb, and Zn concentrations correlate negatively with SBD, pH, AP, AK, and SOM but not AN. SBD showed significant negative correlation with heavy metal concentrations. These results indicate that soil quality parameters can be affected by heavy metal enrichment. Higher levels of heavy metal concentrations are associated with lower AP, AK, and SOM. Lower SBD values lead to greater porosity and greater potential absorption of heavy metals during soil nutrient absorption. Results also suggest that higher heavy metal concentrations in non-subsidence area soils relative to that measured in soils from subsided areas may result from lower SBD values in the latter. The SBD parameter may thus influence soil heavy metal content.

Comprehensive Evaluation of Soil Quality

The membership function clarifies functional relationships between evaluation indices and results by reconciling dimensions and scales of the evaluation index to make evaluation indices comparable. In graphical terms, points on the radar chart closer to the origin indicate lower soil quality for the index indicated by each axis. Points further from the origin indicate higher soil quality for that index. Fig. 5 shows mean membership values for the six soil fertility indices of

Table 8. Correlations between soil fertility index and heavy metal concentrations.

| | SBD | pH | AN | AP | AK | SOM |
|----|----------|--------|-------|--------|--------|--------|
| Cd | -0.271* | -0.092 | 0.063 | -0.201 | -0.058 | -0.178 |
| Cu | -0.337** | -0.176 | 0.140 | -0.056 | 0.177 | 0.022 |
| Pb | -0.283* | -0.067 | 0.060 | -0.160 | -0.076 | -0.166 |
| Zn | -0.320* | -0.112 | 0.098 | -0.160 | -0.003 | -0.134 |

* indicates correlations significant at 0.05 level (double-tailed).

** indicates correlations significant at the 0.01 level (double-tailed).

SBD, pH, SOM, AN, and AK. The non-subsidence area samples gave higher values for these parameters than the subsided area. Average AP membership values for non-subsidence areas fell below those measured from subsided areas. Overall, SBD from subsided areas gave the lowest membership value.

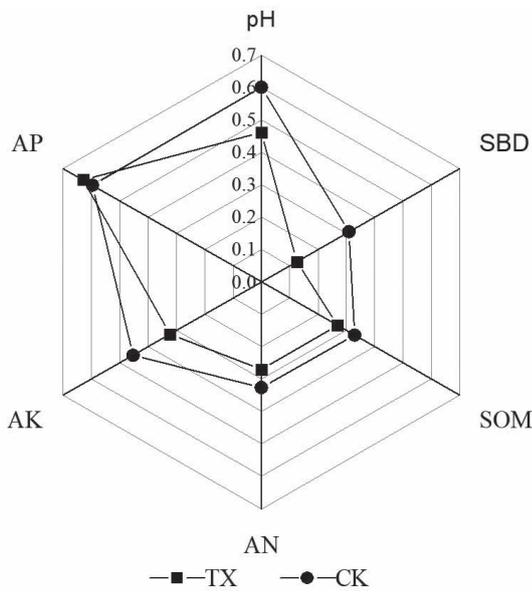

Fig. 5. Average membership values for soil fertility indices.

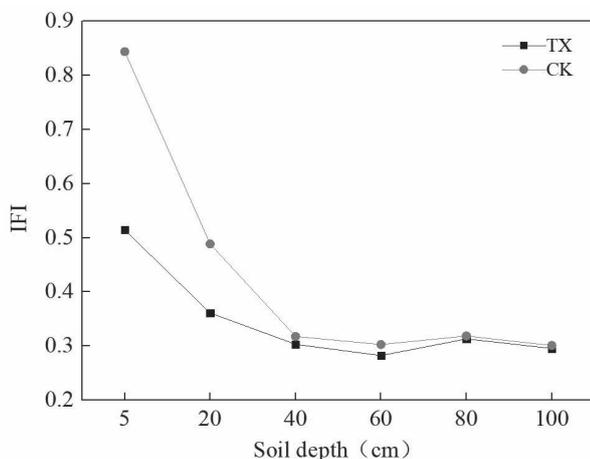

Fig. 6. Changes in IFI with soil depth.

Fig. 6 shows Integrated Fertility Index (IFI) values calculated using fuzzy mathematics for both subsided and non-subsidence areas. Above 40 cm depth, IFI values decline rapidly with depth for subsided and non-subsidence areas. Below 40 cm, the IFI shows slight decreases and occasional slight increase with depth for both subsided and non-subsidence soils. In spite of their similar patterns with depth, the non-subsidence area gave higher IFI values than those measured from the subsided area. These results suggest a longer duration of time necessary to restore surface soil quality to its original state for the subsided area. One-way ANOVA results indicate that significant differences in available soil nutrients and SOM between surface and deep layers cause the observed variation in IFI with depth. However, variation in average membership values for SBD, pH, and AK may also contribute to variation in IFI between subsided and non-subsidence areas.

Evaluation of Soil Heavy Metal Pollution

The Bulianta Mine is located in a semi-arid to arid steppe or desert steppe environment with low vegetation coverage and strong wind and water erosion. The environment is fragile with respect to certain perturbations. Soil types consist primarily of aeolian soil and sandy loam. The pH values measured from soils generally exceed 7.5, whereas Inner Mongolian soils typically exhibit relatively low pH values. National initiatives seek to actively monitor and manage soil erosion in the study area [39]. Using the Primary Standard as a reference value, the single factor index and the Nemerow comprehensive pollution index were used to evaluate the heavy metal pollution of soils for both subsided and non-subsidence areas (Table 9). Both subsided and non-subsidence areas showed single factor index values for elements that ranked as Pb>Zn>Cd>Cu. Single factor index values for Cd and Cu fell below one but exceeded one for Pb and Zn. Therefore only Cd and Cu values met the Primary Standard. The Nemerow comprehensive pollution index values for the subsided area fell within a warning envelope but pollution levels still categorized as 'clean'. The comprehensive pollution index for the non-subsidence area exceeded that of the subsided area with the former categorizing as having 'light' levels of pollution.

Table 9. Soil heavy metal pollution estimates.

| Sample | Single-factor index (P_i) | | | | Nemerow comprehensive pollution index (P_N) | Pollution level |
|--------|-------------------------------|------|------|------|---|-----------------|
| | Cd | Cu | Pb | Zn | | |
| TX | 0.72 | 0.64 | 1.05 | 1.00 | 0.97 | Clean |
| CK | 0.87 | 0.80 | 1.22 | 1.25 | 1.16 | Light pollution |

Table 10. Estimates of potential ecological risk based on heavy metal values.

| Sample | Potential ecological risk coefficient (E_r^i) | | | | Comprehensive pollution degree (C_p) | Potential ecological risk index (RI) |
|--------|---|-------|-------|-------|--|--------------------------------------|
| | Cd | Cu | Pb | Zn | | |
| TX | 86.95 | 8.10 | 10.93 | 1.77 | 8.47 | 107.76 |
| | Heavy | Minor | Minor | Minor | Medium | Minor |
| CK | 104.00 | 10.09 | 12.63 | 2.22 | 10.23 | 128.94 |
| | Heavy | Minor | Minor | Minor | Medium | Minor |

Table 10 lists potential ecological risk index estimates for soils from both subsided and non-subsidence areas. The potential ecological risk coefficient for elements ranked as $Cd > Pb > Cu > Zn$. Of these, Cd gave the largest potential ecological risk coefficient for both subsided and non-subsidence areas. The potential ecological risk coefficients for Cd categorized as a 'heavy' ecological hazard while coefficients for Pb, Cu, and Zn categorized as 'minor' ecological hazards. The Cd concentrations in soils analyzed significantly exceeded background values for Inner Mongolian soils and Cd also carried a higher biotoxicity coefficient. In summary, risk indices indicate minor ecological hazards for the study area while the comprehensive pollution degree indicates a medium level ecological hazard. Cadmium in soils contributes to the elevated potential ecological risk. The above results also show that heavy metals in the study area soils remain elevated even after 15 years of restoration. The long term persistence of hazards require monitoring and further mitigation.

Discussions

Effects of Subsidence on Soil Fertility Index

Soil in subsided or subsiding areas settles due to gravity, ground strength, and soil properties. Wind and water erosion can fill fissures and small gaps in the soil and increase compaction [40]. The research described here found that SBD in the subsided area exceeded that measured from the non-subsidence area. Differences increased with increasing soil depth. Wang et al. [41] described similar changes in soil physical and chemical properties after subsidence associated with the northern Shenmu mining area. In their study, soils from the subsided area exhibited higher pH values than those measured from the non-subsidence area. The pH of

deeper soil exceeded values of 8.5 exhibiting an alkaline chemistry similar to that described here. Alkalinity may result from lack of rainfall and high evaporation in arid and semi-arid areas. Salts donate hydroxide ions that accumulate in soil and groundwater. Fissures from subsided and subsiding areas can intensify soil moisture loss and thereby enhance soil salinization [42].

In this study, AN, AP, AK, and SOM in soil collected from subsided areas fell below that measured from soils collected from non-subsidence areas. The low vegetation coverage for subsided areas may limit sources of SOM in the soil, reduce other soil nutrients, and promote soil degradation [43]. SOM content in the surface soil significantly exceeds that measured from deeper layers. Accumulation of SOM in the surface soil due to vegetation cover may contribute to this effect. Restricted microbial activity in deeper layers may further hinder decomposition of soil organic matter [44]. AK and SOM contents tend to decrease with increasing soil depth. Meanwhile AP content increases with soil depth perhaps due to the poor phosphate fixation and buffer capacity of the sandy soils that characterize the study area. These limit AP transfer into deep soils with surface cracks [45]. For this study, soils were sampled during the rainy season which may have caused the initial decrease and subsequent increase in AN with depth observed among soils in the subsided area. This pattern contrasted that observed for the non-subsidence areas, which showed an initial increase and subsequent decrease in AN with depth. Rainfall may have enhanced formation of subsidence cracks which in turn enhanced leaching of nitrogen and transport to deeper soil layers.

Effects of Subsidence on Soil Heavy Metal Content

Presently, most studies focus on heavy metal pollution in the form of Cu, Zn, Pb, Cd, Ni, and Cr

concentrations in soils around mining areas. However, different studies have reported differing degrees of accumulation and impact [46]. This study reports soil Cd, Cu, Pb, and Zn concentrations that all exceeded background values for Inner Mongolian soils by a factor of 2-3. Results reported here also exceeded those reported for a cultivated soil near the Daliuta Coal Mine [47] by a factor of 2-3. Generally speaking, after adsorption by clay minerals in surface layers, heavy metals do not tend to migrate [48]. However, soils analyzed here show increasing heavy metal concentrations with depth possibly due to strong wind and water erosion. Transport and deposition of coal dust due to wind action may increase heavy metal input to soils which in turn experienced enhanced heavy metal leaching [49]. This study found lower heavy metal concentrations in soils from subsided areas relative to those analyzed from non-subsidence areas. Transport routes north of the slope analyzed as the non-subsidence area may have contributed to this effect. Along with transport vehicles, coal gangue in the mining area may have served as a source of wind-transported coal dust.

Conclusions

(1) Mean SBD values for the study area exceeded 1.55 g/cm³. Soils were compacted and showed pH values ranging from 7.06 to 9.34. The AN, AP, AK, and SOM contents of deeper soil layers place them at “urgent shortage” levels according to soil standards. Soil profiles showed significant variation in AP, AK, and SOM with depth ($P < 0.05$). The AP, AK, and SOM contents tend to decrease with depth. The AN, AP, AK, and SOM contents for the subsided area fell below values measured for the non-subsidence area. Samples from a given soil layer depth did not show significant variation in pH, AN, AP, or SOM between the subsided and the non-subsidence area ($P > 0.05$).

(2) The Cd, Cu, Pb, and Zn concentrations measured from the study area all exceeded the natural background values for Inner Mongolian soils by a factor of 2-3. Heavy metals did not exceed secondary soil environmental quality standards however. Soils from the subsided area showed lower Cd, Cu, Pb, and Zn concentrations than the non-subsidence area. Soils from both subsided and non-subsidence areas showed an inflection point with sharp decreases in heavy metal concentrations above 40 cm depth and more gradual variation below this depth.

(3) Soils from the subsided area gave IFI values from 0.17-0.41, while those from the non-subsidence area gave IFI values from 0.42-0.85. The subsided areas gave relatively poor estimates of soil quality. The Cd concentrations measured from the study area gave the largest potential ecological risk coefficients. Parameters from the subsided and non-subsidence areas gave Potential Ecological Risk Index values of 107.76 and

128.94, respectively, which indicate minor ecological hazard.
