## Abstract

This article addresses the issue of VOC emissions from upholstery materials (natural leather) used for the manufacturing of upholstered furniture. The main intention of this paper is to compare VOC emissions released from different types of natural upholstery leathers. This research has assessed the impact of various factors (e.g. the organic origin of leather, the type of tanning, the type of upholstery leather and the leather finish etc.) on the amount of VOC emissions from natural leathers used for the production of upholstered furniture. 1 m<sup>2</sup> samples of natural leather were prepared for testing before being placed into a small test chamber (1 m<sup>3</sup> volume). VOC emission measurements were taken in a small test chamber with predefined conditions (an ambient temperature of 23°C and 50% relative air humidity). With the use of sorbent Tenax TA were, the values of VOC emissions released by the test sample of different types of leather into desorption tubes was then recorded. VOC emissions were analysed in an Agilent GC 6890 N gas chromatograph using an Agilent 5973 Network mass spectrometer using cryofocusing, thermal desorption and a GC-MS data library (NIST 05). The analyses conducted provide qualitative and quantitative data regarding the concentration of selected VOC representatives measured in µg.m<sup>-3</sup>. The quantitative difference in all emitted organic compounds is shown by the measured values of the TVOC parameter.

**Keywords:** VOC emissions, natural upholstery leathers, indoor air

## Introduction

The indoor air pollution comes from sources inside the building, such as adhesives, carpeting, wooden or upholstery furniture and wood products or cleaning products, which may emit volatile organic compounds (VOCs) [1-4]. However, the outdoor air that enters the building can also be the main source of indoor air VOC pollution [5]. Therefore, if an appropriate ventilation

rate with good quality outdoor air is applied to the dwelling, VOC concentration could be maintained in an acceptable level [6]. VOCs originate from both indoor and outdoor sources [7]; they are of particular concern due to their potential impact on human health. Formaldehyde and benzene [8], for example, are some of the most studied pollutants since they are classified in Group 1 of human carcinogens by the International Agency for Research on Cancer [9]. For many of these chemicals, the risk on human health and comfort is almost unknown and difficult to be predicted because of the lack of toxicological data. In the frame of the INDEX project [10] the existing knowledge worldwide

\*e-mail: petr.cech@mendelu.cz, xstadnik@mendelu.cz

has been assessed in terms of type and levels of chemicals in indoor air, as well as, the available toxicological information. It was concluded that VOCs such as benzene, formaldehyde, acetaldehyde, toluene and xylenes have to be considered as priority pollutants with respect to their health effects [11]. On the other hand, chemicals such as limonene and  $\alpha$ -pinene require further research with regard to human exposure or dose response and effects.

The main sources of aldehydes in homes include building materials, hardwood, plywood, laminate floorings, covering upholstery materials, adhesives, paints and varnishes and in some cases they are products of ozone-initiated reactions [12, 13]. For example, interior coatings can increase indoor air pollution due to VOC emissions [14]. Some of the major VOCs emitted from an oil-based varnish were ethylbenzene, m,p-xylene, o-xylene and formaldehyde [15].

Soft furniture such as sofa, as an important part of civil furniture, has become one of the major sources of indoor air pollution. Due to the advantage of abundant resources and efficient function, leather has been the common raw and auxiliary materials of soft furniture [16].

Research study on the release of emissions Volatile Organic Compounds (VOCs) in natural leather samples by emission test chamber method found 21 kinds of VOCs detected from leather seat samples, including several types of aldehydes, ketones, aromatic hydrocarbons, alkanes, lipids etc [17]. The release trend of major volatile organic compounds in leather seats is consistent with the trend of total volatile organic compounds (TVOC). Both have shown a tendency of release rate from fast to slow and finally achieving a stable release [18].

One of the potentially important sources of organic emissions in leather seats comes from leather and other raw and auxiliary materials [19]. This may be because part of solvents, crosslinking agents and synthetic monomers remain in leather products after the pre-treatment processing when a large number of additives (degreasing agent, crosslinking agent, etc.) and organic solvents (toluene, N,N-dimethyl formamide, etc.) are used [20]. Another experimental study reports the presence of specific chemical substances such as: 1,2-propanediol, 1-methoxy-2-propanol, N-ethyl-2-pyrrolidone in natural upholstery leather samples [21].

## Material and Methods

This research describes the VOC emissions emitted from covering materials used for upholstery furniture production, especially nature leathers. The main goal of this contribution is comparison of VOC emissions emitted from different types of nature upholstery leathers. This research judged the influence the impact of different factors (such as: animal origin, type of tanning, type of upholstery leathers etc.) on amount VOC emissions from natural leathers, that use for upholstery furniture production.

The select covering materials (natural leathers) were taken from the normal manufacturing process, wrapped in aluminium foils and delivered to the test laboratory. Natural leather samples were prepared from different type of materials in depending on these factors (animal species, type of tanning, type of upholstery leather).

The samples were formatted to the required sizes (710 x 710 x 1 mm) and then were divided into three groups depending on monitored factors. The first sample from tested samples was inserted into the test chamber (ČSN EN ISO 16000-9) immediately after unpacking from aluminium foil. The parameters of tested upholstery leather samples are shown in Tables 1 to 3.

Then we started to collect VOC emission emitted by the tested sample into the desorption tubes on the sorbent Tenax TA (porous polymer based on 2,6-diphenyl oxide with a grain size of 0.18-0.25 mm) [22].

The air sample in desorption tube with the captured sample of VOC emissions is then analysed in a gas chromatograph with a mass spectrometer and thermal desorption.

The conducted analyses provide qualitative and quantitative data on the concentrations of selected VOC and the total volatile organic compounds (TVOC) in  $\mu\text{g}\cdot\text{m}^{-3}$ .

- The influence of an organic type of leather (of animal origin) on VOC emissions
- The influence of different types of tanning (chrome-plated or tanned leather) on the amount of emission VOC emissions
- Comparison of VOC emissions from different types of upholstery leathers

### Methodology of Quantitative and Qualitative Determination of VOC Emissions

Quantitative and qualitative determination of VOC emissions is performed on tested samples of covering materials especially on natural leathers. The effect of climatic conditions is also detected in the tested materials before the sampling of VOC emissions. The tested materials will be evaluated according to the time (age) from the date of production in the following time interval for 1, 3, 7, 28 and 120 days after the insertion of the samples into the VOC TEST 1000 small-space chamber.

The part of the measurement of VOC emissions is also the determination of total volatile organic compounds called TVOC (Total Volatile Organic Compounds). TVOC measurement is enabled by implementing an analytical and evaluation method within GC-MS.

### Air Samples

In the present study, air samples from tested samples were collected onto Tenax TA adsorbent (sampling rate 200 mL min<sup>-1</sup>, time 180 min.) from small space chamber (a volume 1 m<sup>3</sup>). Air samples were analysed with a gas chromatograph (HP 6890) equipped with a mass selective detector (MSD 5973) after thermal desorption at 250°C for 3 min (Scientific Instrument

Services TD4). The column was HP-5MS (column length 30 m, i.d. 0,25 mm, film thickness 1 µm), and the identification of the compounds was accomplished by retention times, standard compounds, and GC-MS data library (NIST 05).

The total VOC emission was first calculated by combining the peak areas of all identified compounds, after which the relative proportion of individual compounds from the total emission was calculated. The TVOC value is defined to be the integrated detector response value in toluene equivalents of compounds eluting between and including C<sub>6</sub> to C<sub>16</sub> as given in ISO 16000-6.

### Evaluation of VOC and VVOC

The internal standard (D10-o-Xylen) method is used for the evaluation. Individual VOCs, VVOCs are evaluated by SIM recording. The results are evaluated in the ChemStation software environment after the completion of gas chromatograph analysis. The calibrated compounds are identified by the retention times, target and control ions in the SIM record and the software carries out the quantification of the analyte (ng.tube<sup>-1</sup>). The results are obtained from the report of the measured data of VOC and VVOC substances followed by the conversion to weight concentration (µg.m<sup>-3</sup>). The calculation is carried out according to Equation 1.

$$\rho_x = \frac{m_F}{V}$$

In which:  $\rho_x$  is the mass concentration of the analyte in the air sample ( $\mu\text{g}\cdot\text{m}^{-3}$ )

$m_F$  is the amount of analyte captured on the tube (ng)

$V$  is the collected air volume (liters)

## Results and Discussion

This research study focused on the issue of VOC emissions from natural leathers used for the manufacture of upholstered furniture. Emissions from volatile organic compounds from different types of upholstery leather, in relation to the factors observed, were compared with the GC-MS analysis. VOC emissions from test samples were measured as a function of time (the time since insertion of the test sample into the test chamber) according to the standard ČSN EN ISO 16000-9.

The experimental part of this study was divided into three parts:

- To determine the influence of an organic type of leather (of animal origin) on VOC emissions.
- To determine the influence of different types of tanning (chrome-plated or tanned leather) on the amount of VOC emissions.
- To compare the VOC emissions from different types of upholstery leather.

The results of VOC emissions from natural upholstery leather samples in relation to animal species are shown in Tables 4-6. The test results show the measurement of more than 40 types of VOC released from the leather samples, including several types of aromatic substances, aldehydes, terpenes, and chemicals typical from natural leathers, such as: propylene glycol 1-methyl ether (synonym: 1-methoxy-2-propanol, CAS no. 107-98-2), Propylene glycol (synonym: 1,2 propanediol, CAS no.: 57-55-6); dipropylene glycol monomethyl ether (DPGME, isomer-1, CAS no.13429-07-7) [23].

- a) The influence of an organic type of leather (of animal origin) on the amount of VOC emissions.  
 b) The influence of different types of tanning (chrome-plated or tanned leather) on the amount of emission VOC emissions.

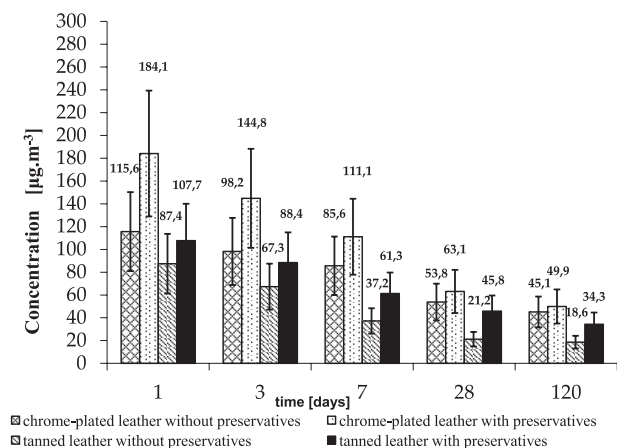

Fig. 1. 1-Methoxy, 2-propanol from natural leathers based on different type of tanning.

Fig. 2. Butoxy-Ethanol from natural leathers based on different types of tanning.

Fig. 1 shows the influence of different types of tanning from natural leathers on the quantity of emissions VOC, especially concentration of 1-Methoxy, 2-propanol. The highest concentration of 1-Methoxy, 2-propanol was found from chrome-plated leather with preservatives at measurements after 1 day in amount over 184  $\mu\text{g.m}^{-3}$ .

Fig. 2 presents the different types of tanning from natural leathers on the quantity of emissions VOC, especially the concentration of Butoxy Ethanol. The highest concentration of Butoxy-Ethanol was found from tanned leather with preservatives at measurements after 1 day.

Fig. 3 presents data of TVOC (Total Volatile Organic Compounds) from different types of tanning from natural leathers. The highest amount of TVOC emitted by tanned leather with preservatives, especially at measurements after 72 hours.

- a) Comparison of VOC emissions from different types of upholstery leathers.

Fig. 4 there presents different types of upholstery leathers on content of emissions VOC, especially of emissions of 1\_Methoxy\_2\_Propanol. The highest

Fig. 3. TVOC from natural leathers based on different type of tanning.

concentration of 1-Methoxy, 2-propanol was found at measurements after 1 day from chrome-plated leather\_4 in amount over 36  $\mu\text{g.m}^{-3}$ .

Fig. 4. 1-Methoxy, 2-propanol from different types of upholstery leathers.

Fig. 5. Butoxy-Ethanol from different types of upholstery leathers.

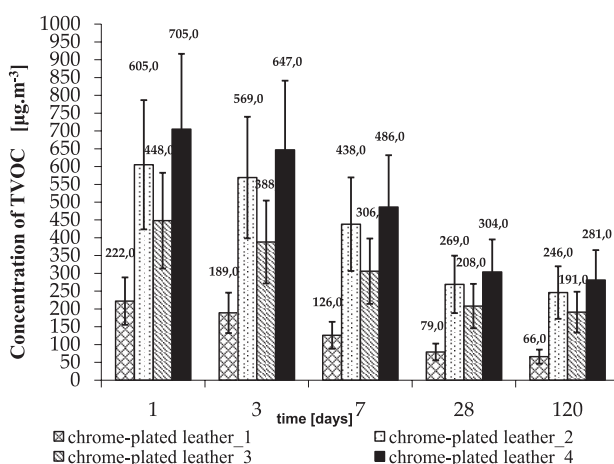

Fig. 6. TVOC from different types of upholstery leathers.

Fig. 5 shows the influence of different types of upholstery leathers on content of emissions VOC, especially emissions of Butoxy-Ethanol. The highest concentration of Butoxy-Ethanol was found at measurements after 1 day from chrome-plated leather no. 4 in amount over 429  $\mu\text{g.m}^{-3}$ .

Fig. 6 presents data of parameter TVOC, emitted by different types of upholstery. Parameter of TVOC is describing the total content of Volatile Organic Compounds emitted by selected species of upholstery leathers in depends on time. The highest values of TVOC were measured at measurements after 1 day from leather no. 4 in amount 705  $\mu\text{g.m}^{-3}$ , followed by values of concentrations TVOC emitted by chromed leather no. 2 (in amount 605  $\mu\text{g.m}^{-3}$ ).

Based on the results presented in this article, we are able to assess the impact of VOC emissions released from the respective tested materials.

*The Influence of the Type of Natural Leather (Animal Origin of Leather) on the Amount of VOC Emissions*

Tables 4-6 show the concentration of VOC emissions from natural upholstery leather in relation to the animal species (buffalo, cow and pig leather). One of the main compounds found in our collection of natural leather VOCs was propylene-glycol-1-methyl ether (synonym: 1-methoxy-2-propanol, CAS no. 107-98-2). This chemical substance is widely used in primers, highly viscous spray paints and bonding agents in formulated topcoats as constituent additives, or is mainly used in final leather surface finishes. The upholstery leather samples tested released other typical substances such as propylene glycol (synonym: 1.2 propanediol, CAS no.: 57-55-6); dipropylene glycol monomethyl ether (DPGMME, isomer-1, CAS No.13429-07-7). Propylene glycol is a chemical used mainly in the surface finish process and functions as a coalescence substance for coating applications. Concentrations of other individual volatile organic compounds (VOC) are very low and their values are comparable to background values (from 0.4  $\mu\text{g.m}^{-3}$  for terpenes – to almost 12  $\mu\text{g.m}^{-3}$  for aromatic chemicals, especially toluene). The values of the TVOC (total volatile organic compounds) parameter are not too high (the highest TVOC value was found in natural buffalo hide in quantities above 500  $\mu\text{g.m}^{-3}$ ), but TVOC values decrease depending on the measurement time [24].

*The Influence of Different Kinds of Tanning (Chrome-Plated or Tanned leather) on the Amount of VOC Emissions*

The results regarding respective chemicals are shown in Figs 1-2, which demonstrate the influence of different kinds of tanning from the tested materials (natural leather) on the amount of volatile organic

compounds emitted, especially solvents – namely 1-methoxy, 2-propanol, and butoxyethanol in relation to time, in the course of one month. The measured data show the dependency of the concentration of 1-methoxy, 2-propanol on the type of tested materials. The highest concentration of 1-methoxy, 2-propanol was found when measured after 1 day from chromed leather with preservatives, in an amount greater than  $184 \mu\text{g}\cdot\text{m}^{-3}$ . But the concentration of butoxyethanol was found only in the amount  $28.7 \mu\text{g}\cdot\text{m}^{-3}$  from chrome-plated leather with preservatives when measured after 1 day [25].

The data measured reveal the minimal impact of various tested materials on concentrations of BTEX and terpene substances. The concentration of these VOCs was very low, which means that the amount was below the level of quantification (LOQ). The concentration of emitted compounds decreases with time [26].

The values of the so-called total volatile compounds (TVOC) are among the key observed parameters. TVOC represents the total amount of VOCs emitted from the respective materials tested. Fig.3 shows the influence of the different materials tested on the total amount of VOC emitted in relation to measured time. The highest TVOC values were recorded in a measurement taken after one day from chromium-plated leather with preservatives in the amount of  $383 \mu\text{g}\cdot\text{m}^{-3}$ , followed by the values of TVOC concentrations emitted by chrome-plated leather without preservatives (in the amount of  $366 \mu\text{g}\cdot\text{m}^{-3}$ ) [27, 28].

#### *Comparison of VOC Emissions from Different Types of Upholstery Leather*

The chamber test showed differences in the concentration of reactive chemicals from different sample types of natural upholstery leather. The tested samples emitted very high concentrations of butoxyethanol and low amounts of 1-methoxy, 2-propanol. The highest values of VOC emissions were released from natural leather no. 4. The highest concentrations of 1-methoxy, 2-propanol were found only in the amount above  $36 \mu\text{g}\cdot\text{m}^{-3}$ , whereas the highest concentration value of butoxyethanol was detected in the amount above  $629 \mu\text{g}\cdot\text{m}^{-3}$ . These test substances were not randomly selected, because 1-methoxy, 2-propanol (Fig. 4) is a typical compound contained in composite coatings as a constitutional compound or is used especially in leather surface finishes [29]. While butoxyethanol (Fig. 5) was found in very high concentrations from the tested samples, the concentrations of BTEX compounds and especially terpene substances were, on the other hand, very low and their values are comparable to the background values (from  $0,4 \mu\text{g}\cdot\text{m}^{-3}$  to  $4 \mu\text{g}\cdot\text{m}^{-3}$ ) [30].

The results in Fig. 6 show that the trend of releasing TVOC concentrations is in line with the trend of several main volatile substances, such as 1-methoxy,

2-propanol, butoxyethanol, BTEX compounds, and terpenes [31]. All displayed an emission trend in which the concentration decreased with time, eventually reaching a stable level.

## Conclusions

The main objective of this research was to determine the influence of various factors (e.g. the animal species, method of tanning, type of natural leather, etc.) on the amount of VOC emissions used to manufacture upholstered furniture.

The test chamber results showed that the concentrations of VOC emissions from the respective materials tested are impacted not only by the type of natural leather, the animal species or the method of tanning, but also by the different type of the surface treatment used for the leather finishing.

One of the main compounds found in our collection of VOC from natural leather was propylene-glycol-1-methyl ether. The upholstery leather test samples released other typical substances, such as propylene glycol and dipropylene glycol monomethyl ether.

## Acknowledgements

The authors are grateful for the support of the Specific University Research Fund of the FFWT Mendel University in Brno of the project „IGA LDF\_VT\_2018002, „The covering materials used for upholstery furniture as a source of emission of VOC and odour in interior “for the financial support.
