Abstract

Polycyclic aromatic hydrocarbons (PAHs) are contaminants widespread in the environment and vehicular emissions have long been recognized as the most important anthropogenic sources of PAHs in urban air. Polycyclic aromatic hydrocarbons (PAHs) emitted in the exhaust gases of diesel and petrol engines using different fuels were quantified. Size fractionated chemical analysis of particles in vehicle emissions were carried out by sampling with an electrical low pressure multi-stage impactor ELPI. The mean concentrations of total PAHs adsorbed onto the particulate matter in the range of 0.03-0.25 μm emitted from the exhaust gases were 48.3, 128.2 and 83.0 $\text{ng}\cdot\text{m}^{-3}$, respectively from three kinds of diesel fuels. Results indicated that PAHs present in the last two fraction (0.17-0.25 μm) have the highest contribution in the total content of these compounds. In the collected fractions of particulate matter emitted in gasoline engine exhaust 12 compounds were identified in the 0.25 μm fraction and 9 PAHs in the 0.17 μm fraction.

Keywords: PAHs, exhaust gases, diesel and petrol engines, anthropogenic sources, particular matter

Introduction

Emissions from motor vehicles have substantially changed over the last decade because of new fuels, changed engine designs, and improved emission-control technology. Engine exhaust gases form a mixture of substances in various states. Gases are dominant, but liquids and solids from incomplete combustion of fuel and engine oil are also present. Particulate matter (PM) emitted from diesel and gasoline engines is a mixture of

soot and soluble organic fraction, which is composed of an aromatic fraction resulting from unburned hydrocarbons (benzene, toluene, styrene, xylene) from the paraffin acidic phase (cresol, benzoic acid) and the alkaline phase (pyridine, aniline). The remaining components adsorbed at the carbon core include *inter alia* water-soluble sulphates, nitrates, metals, and other carbon particulates. The concentrations, modal structures, and temporal patterns of urban particles are strongly influenced by traffic emissions, which are identified as the main source of particle number in urban environments [1].

Polycyclic aromatic hydrocarbons (PAHs) are contaminants widespread in the environment, and vehicular emissions have long been recognized as the

*e-mail: mapol@ciop.pl

most important anthropogenic sources of PAHs in urban air [2]. They are mainly derived from the incomplete combustion of fossil fuels, wood, and biomass, and from the volatilization of petroleum products. Once released into the air, gaseous and particle-bound PAHs can be transported over a long distance and transferred to other environmental media such as surface soil and water. Due to the carcinogenicity and mutagenicity of some of these compounds – particularly those containing four or more aromatic rings – they have been included in the European Union priority lists of pollutants [3].

Particulate matter with dimensions of 0.1-0.5 μm are very easily absorbed by the body and accumulated within the pulmonary alveoli. They may remain there for hundreds of days, which leads to chronic pulmonary trouble and has a potential carcinogenic effect [4, 5]. In the case of acute exposure, the exhaust gases irritate the oral and upper respiratory tract mucosa, cause headaches, vertigo, and tiredness, as well as nausea. The aerodynamic size of the particulates has an impact on their absorption and accumulation in the body [6].

During recent decades, continuous concern has been raised with respect to PM emitted during the operation of motor vehicles, mainly by diesel engines [7-13]. The World Health Organization (WHO) has reported that diesel engine exhaust is classified as carcinogenic to humans [14]. To assess the potential health hazards resulting from inhalation of PM emitted from engines, it is important to establish their qualitative and quantitative composition and to establish the distribution of hazardous substances in individual fractions, as the aerodynamic size of the particulates has an impact on their absorption and accumulation in the body.

It can be assumed that the concentrations of polycyclic aromatic hydrocarbons and their toxic effects will vary depending on particle size. These of the smallest size are possibly the most important source of PAHs, because the number concentration of particles dominates, and they have the largest specific surface area. The operating conditions of the engine, including its power, speed, and the exhaust gas temperature as well as the properties of the fuel itself (e.g., sulphur content, density, distillation point, and octane index) may have an impact on the chemical composition of the exhaust gases and the aerodynamic distribution of particulate matter [14-19]. Therefore, in this paper particulates were collected from diesel and petrol engines running on three different fuels each. Consider-

ing the increasing importance of small airborne particles for exposure assessment, the objective of this study was to characterize and quantify the main pollutants (i.e., PAHs) emitted in the exhaust gases of diesel and petrol engines. Size fractionated chemical analyses of particles in vehicle emissions were carried out by sampling with an electrical low pressure multi-stage electrical low-pressure impactor (ELPI; Dekati, Finland).

Materials and Methods

Chemicals

Standard PAH mixture and corresponding individual compounds were obtained from Supelco. The standard PAH mixture (EPA 610 Polynuclear Aromatic Hydrocarbons Mix 100-2,000 $\mu\text{g/mL}$ in $\text{MeOH}:\text{CH}_2\text{Cl}_2$, 1:1 v/v) contained naphthalene (NA), acenaphthene (AC), fluorene (FL), phenanthrene (PH), anthracene (AN), fluoranthene (FLR), pyrene (PH), benzo(*a*)anthracene (BaA): chrysene (CH), benzo(*b*)fluoranthene (BbF), benzo(*k*)fluoranthene (BkF), dibenzo(*ah*)anthracene (DBA), benzo(*a*)pyrene (BaP), benzo(*ghi*)perylene (BghiP), and indeno(1,2,3-*cd*)pyrene (IN). We used standard reference material SRM 2975 Diesel Particulate Matter (Industrial Forklift) from the National Institute of Standards and Technology (NIST), U.S. Department of Commerce (Gaithersburg, MD). Acetonitrile, dichloromethane, and methanol were of analytical grade and were purchased from Sigma-Aldrich. We used Milli-Q water, obtained with a Milli-Q system (Millipore, Bedford, MA, USA) for dilution.

Sampling Site

For the presented study we used a diesel engine system from a Skoda Fabia automobile (manufactured in 2007: 2.0 L volumetric capacity and 130 kW of power at 1,400 rpm) and a 1.4 L gasoline engine system of 55kW manufactured in 2009 (complying with the Euro 4 European emission standards). Different diesel fuels used included commercial DIESEL Verva (supplied by the Polish oil company ORLEN), Ultimate (from a British Petroleum station), and Gold (from a Statoil station). We obtained Euro 95 commercial gasoils from three companies (ORLEN, BP, and Statoil). The properties of the fuels used are presented in Table 1. Fuel suppliers assure the high

quality of their products on their websites and noted that sulphur content was not more than 50 mg kg^{-1} (for taking care of a car's engine and helping it to run smoother). During the collection of fine particle fraction engines were run at idle speed without load.

Collection of Samples

PAH samples of particle phase were collected using an ELPI sampling system (Fig. 1) at a temperature below 52°C for five days for 4-5 hours at a flow rate of $30 \text{ L}\cdot\text{min}^{-1}$. Basic parameters of ELPI operations were: impactor output pressure 100 mbar, charging voltage 5 kV, and charging current $1 \mu\text{A}$. The particles were charged by corona charging and subsequently separated in a low-pressure cascade impactor with 13 electrically insulated collection stages. The measured current signals were proportional to the number concentration and size. By using kernel functions in order to account for the charging efficiency dependency on diameter and for the collection efficiencies of the different stages, the number concentration in every channel could be calculated [20]. During operation with a diesel engine, sampled gas was drawn from the tailpipe and diluted in an ejection double-dilutor (Dekati, Finland) that enabled us to control the dilution ratio at around 64.

About 7,200-9,000 L of air was passed through the ELPI sampler every day. Only six impactor stages were considered to be essential since they contributed significantly to the measurement. The engine was launched 15 min. before collecting particle-phase PAHs with fuel corresponding to the cycle of measurements.

Particle phase PAHs were collected on aluminum filters weighed on an analytical electronic balance (Mettler Toledo AT261, Switzerland) before and after each collection. Before each weighing the filters were preconditioned in a desiccator for 10 h to remove moisture. The samples were stored in a refrigerator at 4°C for less than seven days until extraction.

Extraction Procedure

PAHs were extracted from the filters with cold dichloromethane (below 5°C) to prevent their loss by volatilization [21]. A sonic bath was used with closed vials for 30 min. After extraction, samples were evaporated to dryness under a high-purity stream of nitrogen, redissolved in 1 mL of acetonitrile, and then analysed. The standards were prepared by spiking known amounts of the EPA 16 PAH mixture onto the filter. Therefore, no blank correction was applied.

Chromatographic Analysis

The samples preconcentrated in nitrogen atmosphere were separated by using the RP-HPLC method (Elite LaChrom with fluorescence detection (FL) of Merck Hitachi, USA) on the column Pinnacle II PAH 15 cm x 3.2 mm ID with precolumn $20 \times 3.2 \text{ mm ID}$, according to the methods mentioned earlier [21]. The flow rate was $0.97 \text{ mL}\cdot\text{min}^{-1}$ and the injection volume was $10 \mu\text{L}$. Elution was performed with a gradient starting from an eluent composition of 50% acetonitrile in water (up to 5 min). The acetonitrile concentration was increased up to 100% in 25 minutes, and maintained at 100% for 5 min. The wavelength of the fluorescence detector was altered for each PAH [10]. Data was collected and processed with HP ChemStation software. Limit of detection (LOD), which was determined based on blanks analysis, did not exceed $0.1 \text{ ng}\cdot\text{m}^{-3}$. Precision of the method was about 14% and total uncertainty was less than 28%; correlation coefficient was 0.998. For validation of the method we used the standard reference material SRM 2975 (diesel particulate matter). There was no significant difference (confidence interval at 95% using *t*-test) between the obtained results and the certified content.

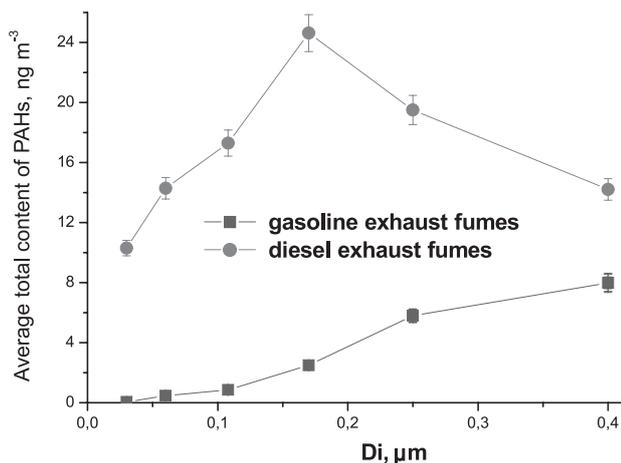

Fig. 2. Distribution of PAHs adsorbed on the fine particles in gasoline and diesel exhaust fumes.

Results and Discussion

Results for Total PAHs

Fig. 2 has presented the average distribution of total PAHs adsorbed on the ultrafine particles in gasoline and diesel exhaust fumes. Particles with a diameter below 0.25 μm were mainly detected in the diesel exhaust, which confirmed our earlier results [11]. The average sizes of particles emitted in gasoline exhaust were smaller than particles emitted in diesel exhaust under similar operating conditions.

The distribution of total PAH concentrations on particulate matter emitted from the used car powered by different diesel fuels is presented in Fig. 3a. Gold fuel generated the smallest PAH emissions, followed by Verva and Ultimate fuels. The mean concentrations of total PAHs adsorbed onto the particulate phase (in the range of 0.03-0.25 μm aerodynamic diameter) using these diesel fuels were 48.3, 128.2, and 83.0 $\text{ng}\cdot\text{m}^{-3}$, respectively. While distribution of total PAH content between different sizes of particles emitted in the exhaust of Verva ON has been almost at the same level, and considerable amounts of these compounds were found in 0.11-0.17 μm (35.2 $\text{ng}\cdot\text{m}^{-3}$) and 0.17-0.25 μm (24.5 $\text{ng}\cdot\text{m}^{-3}$) fractions emitted with Ultimate diesel fuel, which is about 72% in relation to total content.

The distribution of total concentration of PAHs in ultra-fine particulate matter emitted in the exhaust of the petrol engine using oils from different suppliers is presented in Fig. 3b. The obtained results indicate that PAHs present in the last two fractions (0.17-0.25 μm) had the highest contribution in the total content of these compounds.

Results for Individual PAHs

Four PAH compounds were predominantly identified in particulate matter emitted in diesel engine exhaust: fluorene (FL), phenanthrene (PH), pyrene (PY), and benzo(a)pyrene (BaP). The example of the distribution of

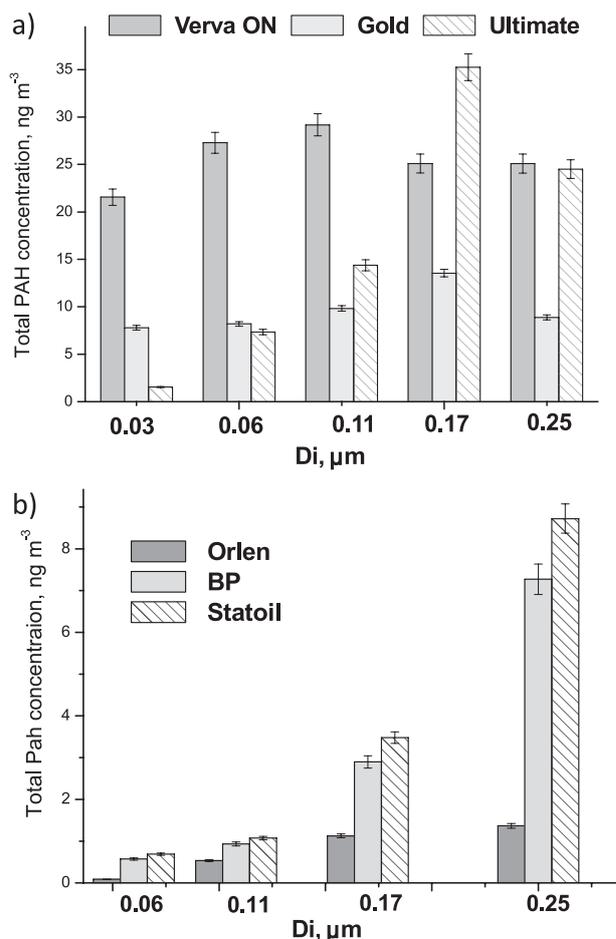

Fig. 3. Distribution of total PAH contents between different sizes of particles emitted in the exhaust of a) diesel and b) petrol engines using different oils.

PAHs identified in individual fractions of particulate matter emitted in diesel engine exhaust running on Verva ON fuel is presented in Fig. 4. On average, the sum of FL, PH, PY, and BaP emission rates amounted to 83.7% of total PAH

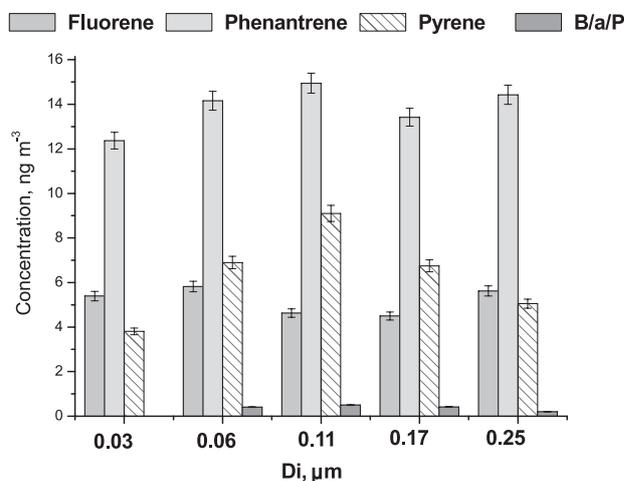

Fig. 4. Concentrations of PAHs identified in ultra-fine particles emitted in the exhaust of diesel (Verva fuel).

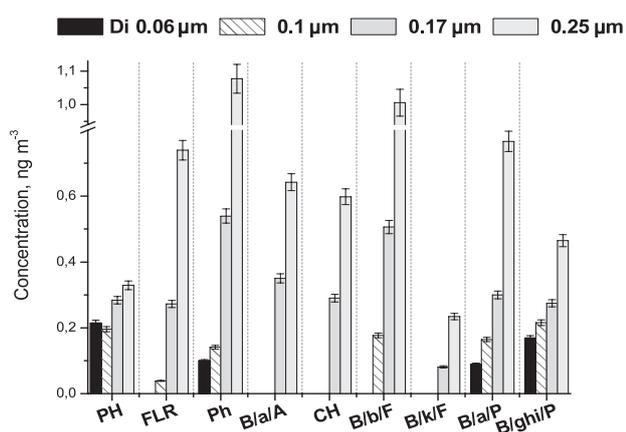

Fig. 5. Emission rates of individual PAH compounds emitted in the gasoline engine exhaust (fuel from BP petrol station).

emissions. Phenanthrene had the highest concentrations (13.4–15.0 ng·m⁻³) in the tests performed for all collected fractions. Its participation averaged 44.8% in relation to the sum of total PAH compounds. Similarly, pyrene and fluorine averaged 21.7% and 16.0%, respectively.

In the case of particulate matter emitted in gasoline engine exhausts, PAH analysis in the collected fractions indicated 12 compounds in the 0.25 μm fraction and nine PAHs in the 0.17 μm fraction. Fig. 5 presents the profile of PAH compounds collected in different ultrafine fractions of particulate matter from the vehicle exhaust using fuel supplied from the BP petrol station. Phenanthrene (PH) and benzo(*b*)fluoranthene (BbF) dominated in these samples, followed by fluoranthene (FLR) and benzo(*a*)pyrene (BaP).

Motelay-Massei et al. [22] suggested that indeno(1,2,3-*cd*)pyrene (IN) and dibenzo(*ah*)anthracene (DBA) could be indicators of vehicular emissions. As diesel exhaust is known to contain more particulate matter than gasoline exhaust, and heavier PAHs are associated with these particles, benzo(*ghi*)perylene, IN, and DBA have been proposed as markers of diesel emissions [23–25]. Tian et al.

[26] also assigned chrysene (CH) for this purpose. However, B*ghi*P, IN, and DBA, as well as benzo(*a*)pyrene (BaP) and benzo(*a*)naphthalene (BaA), were linked with gasoline emission sources [25–27]. Gunawardena et al. [28] concluded that heavy-duty traffic primarily generated five- and six-ring PAHs. They correlated heavy-duty traffic sources with fluorene, dibenz(*a,h*)anthracene, indeno(1,2,3-*cd*)pyrene, and benzo(*ghi*)perylene, whereas acenaphthene, acenaphthylene, phenanthrene, pyrene, benzo(*a*)pyrene, and benzo(*e*)pyrene were correlated with the total traffic volume.

Benzo(*a*)pyrene is considered one of the most carcinogenic PAHs and has been used as an indicator of environmental pollution with polycyclic aromatic hydrocarbons [29]. Table 2 shows the concentrations of this compound in ultrafine particles emitted from diesel and gasoil engine exhaust. In the case of Ultimate diesel and gasoline fuel supplied from Orlen, the contents of BaP were below the limit of detection in all the collected fractions. From the other side, the highest level of that compound was found in the fume exhaust from Gold diesel fuel.

Conclusions

Using ELPI and a multi-day cycle of particulate matter sampling enabled us to separate the particulate matter fractions and establish the distribution of PAH concentrations. The chemical composition of particulate matter emitted in engine exhaust is important due to the issues of environmental pollution. Particulate matter and chemical substances adsorbed onto their surface, such as carcinogenic PAHs, are of great significance because they may have a negative impact on human health due to the place where they accumulate within the human body. The average sizes of particles emitted in gasoline exhaust are smaller than particles emitted in diesel exhaust under similar operating conditions.

Measurements have indicated that the particulate matter in fractions below 0.4 μm is emitted in the diesel

engine exhaust and, to a lesser extent, from the petrol engine. Thus, petrol engines also may be a potential source of environmental pollution with ultra-fine particles. The studies have not indicated the tendency of individual PAH compounds to be adsorbed only on single fractions of particulate matter with specific dimensions.
