Abstract

The preparation of a Gd-doped Ti/SnO₂ anode using the sol-gel method was employed in electrolysis as an advanced treatment of coal chemical industry wastewater. The optimal Gd-doped content and sintering temperature were 2% and 750°C. The electro-catalytic performance was enhanced after doping with an adequate amount of Gd. The doped Gd accelerated the generation rate and content of hydroxyl radicals in the electrolysis process. Gd was mixed into the SnO₂ lattice by means of displacement to refine the SnO₂ crystalline grain. The diminution of grain size supplied more active sites on the electrode surface. The reaction of TOC degradation was between pseudo zero-order and first-order kinetics, and was more inclined to pseudo first-order kinetics. The performance and the stability test demonstrated that the prepared Ti/Gd-SnO₂ anode was competent and that electrolysis with the anode could serve as a technically feasible method with potential application for the advanced treatment of coal chemical industry wastewater.

Keywords: electro-catalysis, Ti/SnO₂ anode, sol-gel, coal chemical industry wastewater

Introduction

Coal chemical industry effluent was considered to be a kind of refractory industrial wastewater with poor biodegradability [1]. The composition of coal chemical industry wastewater is very complex, containing high concentrations of phenols, tar, polycyclic aromatic hydrocarbons, and ammonia, as well as refractory and toxic compounds such as cyanide and thiocyanate [2]. The traditional activated sludge process was widely used in coal chemical plants for wastewater treatment. However, the content of contaminants in effluent after biological treatment was still high, a great distance between the requirements of zero emission of coal chemical industry wastewater [3]. Therefore, advanced treatment was necessary to further remove the toxic and hazardous pollutants in the effluent.

Although the history of electrochemistry spans more than 200 years, its application in wastewater treatment began only 50 years ago. Electro-catalytic oxidation
is a new wastewater treatment technology [4]. As an advanced oxidation process (AOP), electro-catalysis has shown great advantages in terms of wastewater treatment, such as satisfactory treatment effect, no derivative pollution and easy automation that is not attached to other technologies [5-6]. Electrochemical advanced oxidation processes (EAOPs) have received great attention for water remediation, especially in the degradation of recalcitrant organic compounds, because they can generate large amounts of hydroxyl radicals (·OH) for an effective and fast mineralization of toxic and hazardous organic contaminants [7-8]. EAOPs have been regarded as an environmentally friendly technology. Both electrochemical combustion (Eq. (1)) and electrochemical conversion (Eq. (2)) of organics contribute to electro-catalytic reactions [9-10]:

\[
\begin{align*}
MO_x + zH_2O - ze^- & \rightarrow MO_x(\cdot OH)_z + zH^+ \\
R + MO_x(\cdot OH)_z & \rightarrow RO + MO_x \\
MO_x + zH_2O - ze^- & \rightarrow MO_x(OH)_z + zH^+ \\
MO_x(OH)_z - ze^- & \rightarrow MO_x - O_z + zH^+ \\
MO_x - O_z & \rightarrow MO_{x+z} \\
R + MO_{x+z} & \rightarrow RO + MO_x
\end{align*}
\]

(2)

The electrode is the core of electro-catalytic technology in wastewater treatment. Dimension stable anode (DSA) is a type of electrode with a wide application due to its excellent catalytic activity and stability. Various methods for electrode preparation have emerged, such as the impregnation method [11], sol-gel [12], electrodeposition [13], physical vapor deposition, and chemical vapor deposition [14]. Sol-gel is widely used in the preparation of multi-component oxide thin film owing to its high purity, excellent homogeneity, high degree of multi-component scatter, and its easily controlled particle size. The homogeneous dispersion nano oxide layer can be obtained using the sol-gel method.

Rare earth element (REE) shows the ability of catalysis and co-catalysis in many aspects owing to the special 4f electronic structure, and physical and chemical characteristics [15-16]. Conductivity, oxygen evolution potential, stability, and corrosion resistance of the electrode can be improved by doping REE. Different REEs showed different co-catalysis abilities [15, 17]. REE can also affect the formation and growth of crystallite grain in thermal treatment [18]. Stannic anhydride anode-doped gadolinium (Ti/Gd-SnO₂) was prepared by the sol-gel method in this context. Performance of the electrode in advanced treatment of coal chemical industry wastewater was also investigated in terms of COD and chroma removal, and mineralization. Characterization of the anode was obtained with the morphology and component analysis of the electrode surface.

Materials and Methods

Experimental Apparatus

The reactor was a one-compartment electrochemical cell made up of power, electrolytic cell, electrodes, and agitator. The cathode was a stainless steel plate. The prepared Ti/Gd-SnO₂ was employed as the anode. The dimensions of the electrode were 2 × 4 cm. The electrolytic cell was a cuboid vitreous vessel with an effective volume of 300 ml. A constant current was provided by a DC-stabilized power supply (WWL-PS). A magnetic stirrer was equipped with an electrolytic cell to mix the solution. The volume of the reaction solution was 250 ml. The current density used in the experiment was fixed at 15 mA/cm². Anhydrous sodium sulfate was added as background electrolyte with a concentration of 0.5 mol/L.

Wastewater Characteristics

Real coal chemical industry wastewater used in this study was obtained from the full-scale wastewater treatment facility of a coal chemical industry plant in Harbin, China. The wastewater sample was the effluent from the secondary settling tank. The main characteristic parameters are listed in Table 1.

Prepararing the Electrode

Processing the Support

A titanium plate served as the support in preparation of the electrode. Prior to the layer deposition, the titanium plate was pretreated. Pretreatment of the titanium plate included polishing the base and acid washing. Polishing the surface was to get rid of the oxide layer with coarse sandpaper, followed with fine sandpaper. Then the titanium board was washed with hot alkaline solution to wipe off oil. Finally, it was rinsed and etched with oxalic acid to remove the oxide film and enhance adhesion between the titanium plate and the coating. The residual oxalic acid was washed off with deionized water. The pretreated titanium substrate was preserved in anhydrous ethanol.

Preparation of the Electrode

The Gd-SnO₂ sols were prepared from anhydrous SnCl₄, SbCl₃, Gd(NO₃)₃, water, propanol, and isopropanol in the following molar ratio: Sn:Sb = 100 : 6.5. The Gd-doped content (defined as Gd/Sn) was controlled to 1%, 2%, 3%, and 4% by adjusting the amount of

Gd(NO₃)₃. The molar ratio of water, propanol, and isopropanol was 3:3:2. The prescribed amount mixture of SnCl₄, SbCl₃, and Gd(NO₃)₃ was dissolved in the mixture of solvent and an exothermic reaction took place. Then the solution was stirred for 1h to promote the prehydrolysis of the precursor. A certain amount of polyethylene glycol was added as a protective agent to keep from agglomeration. Following the above procedures, clear and homogenous sols were obtained. The sols were painted evenly on the pretreated titanium plate followed by drying at 95°C. The processes of painting and drying were repeated five times. Then the titanium plate was heated at 350°C with a definite annealing temperature for 15 min. We duplicated the whole procedure five times, after which the sample was sintered at a defined temperature with the same annealing temperature for 120 min. 450, 550, 650, and 750°C were employed in the sintering process. Following all the above programs, a titanium anode coated with SnO₂ doping various amounts of Gd was obtained using the sol-gel method. The active material (SnO₂) deposited was about 1.0 mg/cm², calculated by weight difference before and after the preparation procedure and the area of the titanium substrate.

**Analytical Methods**

Samples were taken from the reactor at constant intervals and analyzed immediately after being filtered through 0.45 μm filter paper. COD and chroma were measured in accordance with standard methods. Total organic carbon (TOC) was measured by a TOC analyzer (TOC-CPN, Shimadzu, Japan). UV254 was determined with a UV-Vis spectrophotometer (UV-2550). SEM analysis was performed on a field emission scanning electron microscope (Helios Nanolab600i). XRD spectrum was record on a D/max-rb x-ray diffractometer. Test conditions were: CuKα (0.15405 nm), 45 kV, 50 mA, graphite monochromator, slit DS 1° SS 1° RS 0.15 mm. Fluorescence spectrum was conducted on an RF-6500 fluorescence spectrometer. The polarization curve was recorded on a CHI 832 electrochemical station (CHI Inc., USA) with a single component cell. Pt foil was used as the counter electrode and an Ag/AgCl (saturated KCl) electrode as the reference electrode. The working electrode was the prepared anode constituting a triple electrode system. Test dynamic potential scan rate was 10 mV/s.

**Results and Discussion**

**Effect of Preparation Process on Electro-Catalytic Performance**

**Sintering Temperature**

Anodes prepared at various heating temperatures were applied in advanced treatment of coal chemical industry wastewater. Gd doping content (Gd/Sn) was kept at 4%. Chemical oxygen demand (COD) was employed to characterize the electro-catalytic performance.

The electro-catalytic performance was poor when heating temperature was 450°C (Fig. 1). The effluent COD was 65.18 mg/L for 3h electrolysis, with the removal efficiency of only 44.05%. The electro-catalytic capability was enhanced when heating temperature rose to 550°C, with COD removal efficiency increasing to 63.66%. COD removal efficiency was comparable to the anodes heated at 650°C and 750°C, while the latter was a little higher. The growth of SnO₂ crystal was incomplete at lower heating temperatures, causing few amount of carrier-generated electro-catalysis, high resistance, and poor conductivity. Therefore, electro-catalytic performance of the anode was poor. Higher temperature was in favor of the formation and growth of SnO₂ crystals, inducing better electro-catalytic activity.

**Gd Doping Content**

We investigated electro-catalytic performances of anodes doped in different amounts of Gd heated at 750°C.

The electro-catalytic performances of anodes with various Gd doping contents varied significantly (Fig. 2). Low Gd doping content promoted the electro-catalytic activity of the anode. The optimal Gd doping content was 2% in terms of electro-catalytic performance. At the optimal doping content, COD decreased to 30.08 mg/L for 3 h treatment, with removal efficiency of 74.2%. The electro-catalytic performance worsened when Gd doping content rose. Cell potential difference reflects the stability of the electrode. A small variation of cell potential difference was observed when Gd doping content was low, demonstrating well stability. Cell potential difference rose along with the process of electrolysis when Gd doping content increased, suggesting poor stability. With Gd doping content of 2%, electro-catalytic activity and stability of the anode were both well.
Characterization of the Electrode

Polarization Curves

Polarization curves reflect the characteristic relationship between electrode reaction rate and electrode potential. The tangent line of the later part crossed the abscissa axis (potential axis), and the abscissa value of the intersection was the oxygen evolution potential of the electrode.

The oxygen evolution potential of the Ti/SnO₂ anode was 2.05 V (vs. Ag/AgCl), while the oxygen evolution potential of the Ti/Gd-SnO₂ anode ascended to 2.23 V (vs. Ag/AgCl) (Fig. 3), suggesting that the surface structure and morphology of the electrode changed after the Gd addition.

The degradation of organic compounds depended on the adsorptive hydroxyl radicals on the electrode surface, while oxygen evolution reaction was the main competitive side reaction in the electrolysis process, which could reduce current efficiency and the degradation rate. The higher the oxygen evolution potential, the greater the resistance of the oxygen evolution reaction and the harder...
it occurred. Therefore, the ability to generate hydroxyl radicals was enhanced and electrocatalytic performance was promoted. Moreover, the degradation rate on the electrode surface was faster than the mass transfer rate, resulting in a decrease of reactant concentration near the electrode and causing the fall of the current density. In order to maintain the defined current density, the electrode potential had to rise accordingly. The faster the reaction rate, the greater the elevated amount of electrode potential. The electrode reaction rate sped up with the increase of oxygen evolution potential [19].

**Scanning Electron Microscope (SEM)**

SEM was employed to analyze the morphology of the electrode surface (Fig. 4). Massive blocks with large cracks were agglomerated on the surface of the electrode without Gd doping. A uniform and compact film formed and covered the Ti support commendably when doping with adequate Gd (2%). Substantial tiny cracks lay on the surface layer of the anode with excessive Gd. The results demonstrated that a moderate amount of doped Gd prompted the refinement of crystalline grain. The homogeneous and compact oxide layer prevented the Ti substrate from being corroded into titanium dioxide by the active species generated on the electrode. The poor conductivity of titanium dioxide caused exfoliation of the oxide layer and deteriorated the stability of the electrode. Therefore, an adequate amount of doped Gd not only enhanced electrocatalytic performance but also improved the stability of the anode.

**X-Ray Diffraction Spectra**

We obtained the XRD spectra in Fig. 5 in order to compare the Ti/Gd-SnO₂ and Ti/SnO₂ anodes. In contrast to the noise of the Ti substrate, the (110), (200), and (211) diffraction peaks of SnO₂ in both anodes were still distinguished from the fingerprints of the XRD spectra. The dominant ingredient in the oxide coating was SnO₂ in the tetragonal rutile crystalline phase, as analyzed from diffraction fingerprints. And crystal growth was fine. We did note find diffraction peaks of compounds containing Sb and Gd, and deducing oxides containing Sb and Gd were not generated in the thermal process. This suggests that Sb and Gd were mixed into the SnO₂ lattice by means of displacement or embedding. Diffraction intensity declined and the diffraction peaks broadened after Gd addition, for the reason that the oxides were formed before the annealed process and changed from the amorphous phase to the crystalline phase with increasing temperatures. The crystallite sizes were estimated by Scherrer equation on the (101) peak. And the detail information was listed in Table 2.

The grain size of anodes prepared by sol-gel method was at the nano level. The grain size descended in the thermal process after Gd was doped. The Gd doping changed the nucleation and growth rate of the crystal. The growth rate of the crystal was suppressed by doped Gd. Then the growth rate of the crystal was lower than the nucleation rate, leading to the diminution of grain size. Compared with the process of thermal decomposition, precursor conversion into oxide occurred during the reflux stage and most of the M-O bonds were formed before the calcination step in the sol-gel process [20]. Whatever electrochemical combustion or electrochemical conversion, both demand a great deal of active sites. The active site with high surface energy reacts readily with other atoms to generate stable compounds. The electrode is essentially one kind of solid catalyst, without adjacent atoms on the outward side of the surface. Some chemical bonds toward the space turn into “dangling bonds” that are unsaturated and chemically active. The diminution of grain size supplied more active sites on the electrode surface. Therefore, the doped Gd enhanced the catalytic activity of the anode. In addition, the expansion of the unit cell was observed from the unit cell parameters. The displacement of Sn²⁺ (ion size 0.071 nm) by Gd³⁺ (ion size 0.094 nm) may be the key reason for the expansion.

**Electro-Catalytic Performance**

**TOC Removal**

The anode employed in the treatment of coal chemical industry wastewater was prepared at a sintering temperature of 750ºC with 2% Gd doping. TOC removal efficiency was employed to assess the mineralization rate of organic contamination and investigate the ability to decompose organics of the anode.

Table 2. Analysis of XRD.
TOC in the effluent treated with the Ti/Gd-SnO$_2$ anode was 14.49 mg/L for 3 h electrolysis, with removal efficiency of 60.1% (Fig. 6a), while TOC removal efficiency was 55.1% electrolyzed with an anode without Gd doping. The electro-catalytic performance of the SnO$_2$ anode was enhanced significantly after an adequate amount of Gd doping. The removal of TOC reflected the amount of organic compound that completely mineralized in the wastewater. Electrochemical combustion was heightened due to the doped Gd.

Both pseudo zero-order and first-order fitting were well with linear correlation (Fig. 6, Table 3). Reaction rate constant ($k$) can characterize the electro-catalytic activity of the electrode. The reaction rate constant of SnO$_2$ anode doping adequate Gd was larger than that of the anode without Gd, indicating that doping Gd accelerated the reaction rate of organic degradation and improved electro-catalytic activity. Both pseudo zero- and first-order fittings showed good correlation as judged from the squared correlation coefficient ($R^2$). The squared correlation coefficient of pseudo first-order kinetic fitting was a little higher than that of pseudo zero-order kinetic fitting, deducing that electrolysis reaction was between pseudo zero-order and first-order kinetics and more inclined to the latter.

When the degradation rate of organics reacting on the electrode surface is fast enough, mass transfer becomes a rate-limiting step and electrolysis shows pseudo first-order kinetics. In contrast, the Faraday electrolysis process changes into a rate-limiting step when reaction rate on the electrode surface is slower than mass transfer rate, presenting pseudo zero-order kinetics [21]. Electrolysis is more inclined to pseudo first-order kinetics, suggesting that mass transfer was the rate-determining step in advanced treatment of coal chemical industry wastewater. The major mass transfer mode in the liquid phase includes diffusion, migration, and conversion – all of which are functional in the electro-catalytic reaction [22]. Diffusion was the dominant method of mass transfer on the electrode surface. A reactant was consumed in the electrode reaction and then concentration difference of the reactant emerged between the electrode surface and the liquid bulk, forming the driving force of diffusion. Diffusion flux is proportional to the concentration gradient according to Fick’s first law. The concentration of residual pollutant in the biologically pretreated wastewater was very low, resulting in a lower concentration difference and mass transfer rate. The low mass transfer rate made it the rate-determining step, being inclined to pseudo first-order kinetics.

Chroma and UV254 Removal

The value of UV254 demonstrates the content of aromatic compounds containing C = C and C = O bonds. Chroma is a sensory indicator of water quality. The performance of UV254 and chroma removal for 3 h electrolysis is listed in Table 4.

The removal efficiency of UV254 and chroma were 87% and 81%, respectively, by electrolysis with the Ti/Gd-SnO$_2$ anode. The result illustrates that the Ti/Gd-SnO$_2$ anode was competent and that electrolysis was an effective method for advanced treatment of coal chemical industry wastewater.

The Ability to Generate Free Radicals

Electro-catalytic degradation of organic compounds comprised direct and indirect oxidation processes. Direct

a. values represent the average value ± standard deviation of data obtained from five parallel tests.
Advanced treatment of coal chemical industry wastewater is an important issue to be addressed. This study focused on the electrochemical oxidation of organics by means of AOPs, in which electrochemical oxidation was the Faraday process in which organic compounds directly lost electrons on the electrode surface. Indirect oxidation was mainly the oxidation reaction between organic compounds and active species formed on the electrode surface. The main active species was hydroxyl radicals (·OH). As the active group generated in AOPs, hydroxyl radicals play a vital contribution to the degradation of organics. The ability to produce ·OH was considered to be the index of an electrode to appraise its electro-catalytic performance. Terephthalic acid and ·OH react rapidly into 2-hydroxy terephthalic acid, which generates fluorescence emissions with the wavelength of 425 nm after an excitation by UV of 315 nm. The evolution of fluorescence intensity indirectly reflected the generation content of hydroxyl radicals during the electrolysis process.

The fluorescence intensity ascended during the electrolysis process, as observed in both electrolyzers with Ti/Gd-SnO$_2$ and Ti/SnO$_2$ anodes. A linear relationship was obtained between fluorescence intensity and time, demonstrating that the generation of hydroxyl radicals conformed to pseudo zero-order kinetics. The generation of hydroxyl radicals sped up after Gd doping, illustrating that electro-catalytic activity was enhanced. The result was consistent with that of TOC degradation.

### Stability of the Anode

The measurement of stability employed a high current accelerated life test. Then the lifespan of the electrode was estimated according to empirical formula (3):

$$t = \left( \frac{A_i}{A} \right)^2 \times t_1$$  \hspace{1cm} (3)

...where $A_i$ is the current density in the accelerated life test, $A$ is the actual current density, and $t_1$ is the lifespan obtained in the accelerated life test. The result of the test is listed in Table 5.

The actual service life of the prepared Ti/Gd-SnO$_2$ anode was long enough and reacted to 328.7d, which provided favorable conditions for the practical application of the anode.

Electro-catalysis with the Ti/Gd-SnO$_2$ anode exhibited excellent performance in the advanced treatment of the wastewater, and the Ti/Gd-SnO$_2$ anode showed good stability. In addition, when four pairs of electrodes were employed in the electro-catalysis system, power consumption per ton of wastewater was 1.2 kWh with effluent TOC and COD concentrations of 14.49 and 30.08 mg/L. The results demonstrated that electro-catalysis with the Ti/Gd-SnO$_2$ anode could serve as a technically feasible and cost-effective method with potential applications for the advanced treatment of coal chemical industry wastewater.

### Conclusions

The optimal sintering temperature and doped Gd content of electrode preparation were 750°C and 2%, respectively, in terms of both electro-catalytic performance and stability. A uniform and compact film formed and covered the Ti support commendably after adequate Gd addition (2%), which enhanced anode stability. Gd mixed into the SnO$_2$ lattice by means of displacement suppressed the growth of SnO$_2$ crystalline grain. The diminution of grain size supplied more active sites on the electrode surface. The electrolysis reaction of TOC degradation with the Ti/Gd-SnO$_2$ anode was between pseudo zero- and first-order kinetics, and more inclined to the latter. Mass transfer was the rate-determining step. The doped...
Gd accelerated the generation rate and content of hydroxyl radicals, and therefore improved electro-catalytic activity. The removal efficiencies of UV254 and chroma were 87% and 81% in electrolysis with the Ti/Gd-SnO2 anode. The study demonstrated that the prepared Ti/Gd-SnO2 anode was competent and that electrolysis with the anode could serve as a technically feasible method with potential application for the advanced treatment of coal chemical industry wastewater.
